**48. Empuje y tiro.** Cuando la gravedad sola no se puede utilizar para dar los cortes a los carros (¶ 50), el movimiento de estos debe hacerse con locomotora. A los carros se les puede dar un *empuje* por la loco, y entonces se deja que vayan adonde se quiera y, algunas veces ayudados por una ligera pendiente. Deben estar gobernados por los retranqueros o guardafrenos. También los carros pueden arrastrarse o *tirarse* « haciendo cortes corridos », asi : con el tren en movimiento, se desengancha la loco y sigue corriendo adelante, a velocidad creciente por un desvio o via desocupada; y el desvio se cambia rápidamente a tiempo para que los carros que vienen entren en el desviadero que se quiera. Esto exige cooperación hábil del personal del tren y del patio. Estos métodos aunque censurados y costosos durante la operacion, son no obstante, con frecuencia mas económicos en patios pequeños o de poca importancia, que cualquiera de los métodos siguientes, que son mas costosos para instalarlos y mantenerlos, pero que remuneran bien su costo en patios grandes de mucho tráfico.

**49. Corte con Pértigas.** Por medio de pértigas gruesas, de dos a tres veces el largo del espacio que hay entre dos carros, la loco (algunas veces provista con un carro construido especialmente), y corriendo hacia adelante y hacia atrás en una via paralela) empuja desprendiendo del tren uno ó mas carros cada vez y los manda bajo su propio impulso por los cambios a su destino.

**50.** Patio de clasificacion de **loma ó gravedad.**

En este tipo de patio de clasificacion, el tren se empuja sobre una loma en la via y en ésta se desenganchan los carros, uno ó más a un tiempo, y descienden por gravedad, al lugar que se desee.

**51. Operación.** Un tren entra por las vias de recibo, su loco se desengancha y se manda a una via lateral para proveerse de carbon, etc. Una loco especial de patio viene entonces detrás del tren y lo empuja lentamente hacia adelante, sobre una loma. A medida que un carro, ó juego de carros pasa sobre la loma, se desenganchan. Entonces, sigue por gravedad (generalmente va primero a una báscula de via, en el cual se puede pesar cada carro) y entra en « la via de distribución » que los conduce por desvios a las diferentes vias de clasificación. A medida que cada carro o juego de carros empieza a moverse, puede marcarse con un número o simbolo, indicando su destino, a medida que el carro ó juego de carros desciende por la via de distribución, es anotado por el chuchero* y este le abre el chucho* que le corresponde. Estos carros llevan sus guardafrenos que regulan su velocidad. Las cuestas o lomas y la via de clasificación están dispuestas de tal modo que aseguran el envio de los carros al lugar mas remoto que se desee. El guardafrenos entonces regresa por otro carro o juego de carros. Cuando es hora de preparar un tren desde una o mas vias de clasificacion la « locomotora de camino » retrocede del extremo mas bajo del patio, engancha la coleccion de carros deseada, y entonces sigue al patio de entrega o sigue a la linea principal.

---

* Véase *N. del T.*, pág. 858.

**52. Velocidad de la operacion.** Segun Mr C. L. Bardo, Jour N. Y. R. R. Club, 1903, Dic, un tren de 60 carros, con 50 cortes necesita 2 horas, empujando y tirando : con pértiga, 1 hora, 15 mins; por lomas 30 mins.

**53. Las pendientes** de las lomas en los patios, dependen sobre todo del promedio y máxima resistencia de los carros (generalmente mayor en los carros vacios que en los cargados) por unidad de peso; que depende mucho a su vez del tiempo que los carros han estado parados; de la temperatura (la resistencia es mayor en tiempo frio); de la direccion del viento; de su velocidad máxima probable; del estado de la vía; de las curvas, etc. Vease Resistencia del tren, pp. 1129.

**54.** En la siguiente tabla, la primera linea dá las recomendaciones del manual de la Asen Am Ings de F. C. de 1911. Las otras (de la revista Railway Age Gazette, 1912 Aug 9, pp. 236-9) dán los valores max, promedio, y min informado por Mr. Shelby Saufley Roberts, y representa cerca de treinta patios de lomas ó por simple gravedad. Las pendientes están dadas en ms por cada 100 metros.

| | Primera pendiente desde la cumbre. | Via de distribucion | Patio de clasificacion. |
|---|---|---|---|
| | — | — | — |
| Asen Am Ings F. C..... | 3.00 | 1.00 | 0.50 |
| S. S. Roberts Máxima... | 4.00 | 1.75 | 1.00 |
| — Promedio.. | 2.66 | 0.97 | 0.30 |
| — Mínimo... | 1.00 | 0.50 | 0.00 |

**55.** *Cambios debidos a las estaciones.* Con el objeto de compensar las marcadas diferencias en resistencias, debidas a la temperatura, las pendientes de las lomas o planos inclinados se cambian algunas veces, modificandolas dos veces al año o disponiendo dos lomas una al lado de la otra : una más pendiente para usarla en invierno, y una mas suave para el verano; pero tambien la loma de mas pendiente se puede usar con ventaja en verano para los carros vacios en recorridos dificiles. Véase en el próximo ¶ otro método.

**56.** La *loma mecánica*, trazada por Mr. A. W. Epright, inspector de básculas del F. C. de Pennsylvania consiste esencialmente en un puente formado de dos luces de vigas cortas, el soporte central o del medio, puede ser bajado o levantado por medio de gatos, y entonces se asegura a la altura adecuada con bloques. En uno instalado en el enlace de West Brownsville, Div de Monongahela, cada luz es de cerca de 6 ms, el movimiento del soporte central es de cerca de 20 cm.

**57.** Después de haber pasado la pendiente, es corriente hacer pasar el carro por una

**58. Báscula de via.** Hasta hace poco, muy poca atención se daba al diseño de básculas de via porque han sido mas bien aparatos delicados propensos á descomponerse y á dar lecturas erroneas. No obstante, ultimamente se han producido aparatos mucho mas satisfactorios. Son esencialmente aparatos de grandes dimenciones para pesar grandes masas, en cuyas plataformas se instala la via.

**59.** *Las dificultades* encontradas se han puesto en lista por la comision de la Asen Am de Puentes y Edificios de F. C. como sigue :

Descuido del pesador; equilibrio impropio, otro carro descansando en parte sobre la báscula.

Miscelanea : plataforma trabada, carriles trabados, soportes y piezas rotas, soportes embotados, puntos de apoyo sostenidos en los angulares, espacio insuficiente entre los pies y maderas de la báscula, palancas fuera de linea o flojas, y materias extrañas en fricción con las palancas ó partes de la báscula. Vease tambien ¶ 63.

Muchas de estas dificultades son originalmente debidas á fundaciones insuficientemente firmes.

**60.** *Carriles muertos.* Para evitar el desgaste innecesario de las básculas las locos y carros que no necesiten pesarse pueden, cuando se aproximan a la báscula enchucharse y pasar la fosa de la báscula sobre un par de « carriles muertos » tendidos paralelamente a los carriles de pesar y separados unos 15 cm de ellos, pero, soportados rigidamente sobre postes que pasan por la báscula sin tocarla y descansan sobre los cimientos de la fosa de la báscula; pero las básculas modernas son suficientemente fuertes para soportar todo el tráfico sin dañarse; y los carriles muertos están en desuso, todas las locos y carros pasan sobre las vias de pesar. Los carriles

muertos hacen peligrar la vida del personal de vía, que pueden cogerse los pies entre los carriles de pesar y los muertos, y sus soportes obstruyen el acceso al mecanismo de la báscula.

**61.** « *Carriles-Puente* ». Los carriles de pesar están conectados, algunas veces con los carriles fijos, en cada extremo de la báscula, por pequeños tramos cortos de carriles embisagrados. Esto no solamente evita el golpe causado cuando una rueda salta el espacio entre los extremos del carril fijo y los carriles de pesar, sino que transfiere mas gradualmente la carga a la báscula.

**62.** *Accesorio para desconectar.* El F. C. de Pennsylvania ha empleado un sistema patentado por Mr. A. W. Epright, que consiste en unas coyunturas y pistones, operados por aire o agua, regulados por el pesador usando una válvula de tres pasos, por medio del cual, en un segundo, en el intervalo del paso de dos carros cualquiera, la carga de la báscula y de cualquier carro que siga puede a voluntad quitarse por medio de las coyunturas, o volver a ponerla en la escala de las palancas de la báscula.

**63.** *Trabada de las plataformas.* Esta ha sido causa de frecuentes dificultades y pudiera evitarse haciendo una construccion cuidadosa, evitando que se deforme hacia adentro (a consecuencia de las heladas) de los costados de la fosa; a las caras opuestas se les hace un declive mas ancho abajo que arriba, de modo que los objetos que caigan no se acuñen y se tranquen. Los extremos del carril, aun cuando estén asegurados contra el deslizamiento son propensos a trabarse, bajo los cambios de temperatura; esto puede evitarse insertando puntas o agujas de chucho en los carriles cerca de los extremos de la báscula.

**64.** El *largo de la báscula*, si cada carro que se va a pasar se va a parar en la báscula, debe ser cerca de la longitud del carro que sea mas largo. Si los carros se van a pesar en movimiento, cuando pasen por la báscula, el largo de la báscula debe ser cerca de un tercio mayor.

**65.** *Pruebas.* Las básculas deben probarse periodicamente, digamos cada dos meses, corriendole por encima y parandolos en varios puntos, carros especiales, llamados de prueba, cargados con pesos conocidos. Es preferible que los pesos se puedan variar facilmente con el objeto de ver si las indicaciones de la báscula son exacta y verdaderamente proporcionales a la carga. Muchos ferrocarriles tienen carros especiales con este objeto.

**66.** Es necesario el *desagüe, calefacción* y *alumbrados* de la fosa de la báscula para evitar los perjuicios del agua y las heladas, y para facilitar la inspección y ajuste.

**67.** *Velocidades.* La velocidad de los carros sobre las básculas mientras se pesan, pueden variar entre cero y 9 o 13 kilómetros/hora; cerca de 7 kilóm/hora es lo usual. Tambien se pueden pesar varios carros por minuto; pero el tiempo que se requiere por carro, puede variar, desde 8 segundos hasta varios minutos, aunque aquella rapidez rara vez puede sostenerse.

**68. Clasificación.** A medida que los carros se desconectan del tren, y cuando pasan por la pendiente, los chucheros deben saber para qué linea está destinado cada grupo de carros que se desconecta, con el objeto de que puedan cambiar los chuchos (1) adecuadamente; y el retranquero o guardafrenos de cada grupo de carros debe saberlo también, para que pueda regular la velocidad al pasar por el chucho, y al tener que enganchar con algunos carros mas delante. Algunas veces el lugar a que van destinados se escribe con yeso sobre el cuerpo del carro, otras veces (especialmente por la noche) el guardafrenos informa al chuchero por medio de señales arbitrarias.

**69.** La « *lista de cortes* » recomendada por el Suplemento de 1913 de la Asen Am Ings F. C., Manual de 1911 la forman dos o mas listas duplicadas, dando (1) el número (1.°, 2.°, 3.°, etc.) del corte (2) el número de la via al cual se destina el grupo de carros, y (3) el número de carros en el grupo. Una copia de la lista se le da a cada chuchero interesado y (si se cree necesario) una copia al guardafrenos de cada grupo de carros.

**70.** *Los chuchos* (1) *de patio* (Asen Am Ings F. C. Manual 1911)p ara vias de conexión deben tener *ranas* no mas agudas que el n.° 8. Véase tambien ¶ 57 (Enlaces) en ***Desvios en escala,*** pág. 947.

(1) Véase *N. del T.*, pág. 858.

**71.** *Cambios.* La manipulación de cada cambio (en el patio), por una palanca colocada en el cambio, es barata en su instalación, pero costosa en su manipulación y deficiente en un patio grande, si se compara con el gobierno de numerosos cambios desde una sola torre por medio del equipo usual de cambios y señales. Véase Señales, pags 1059, etc., etc.

**72.** *Compensación de curvas.* Como las pendientes se disminuyen en las curvas, para facilitar las subidas, del mismo modo se aumentan en las curvas de los patios donde va a obrar solo la gravedad, para ayudar a pasar los carros por las curvas. Mr. H. M. North, del F. C. L. S. & M. S., recomienda un aumento de 1/2000 por cada grado de agudeza.

**73. Vias de enlace** son las que contienen los cambios que llevan las distintas vias de clasificación (¶ 74). En patios pequeños, una via de enlace es suficiente : generalmente se desperdicia espacio cuando se sacan mas de 8 o 10 vias de un enlace, y entonces es conveniente usar dos o mas enlaces. Vease tambien ¶ 57, pag. 947.

**74. Vias de clasificación.** Son vias largas paralelas, a las cuales se corren los carros que vienen de los enlaces. En general, cada via de clasificación representa una ruta diferente o diferente destino o dif objeto de tren. Asi, la via n.° 1 puede usarse para carros destinados al F. C. M., via n.° 2 para carros del F. C. N., y asi las demas; o la via n.° 1 para carros destinados a la estacion *P*, la via n.° 2 para la estacion *Q*, etc. y puede por consiguiente formarse un tren tomando carros sucesivamente de la via 1, 2, etc., en tal orden que puedan desconectarse en las estaciones *P*, *Q*, etc., a medida que el tren sigue, y sin dar cortes dobles : o la via n.° 1 puede reservarse para un tren regular o diario, que sale a una hora determinada; la via n.° 2 para un tren especial; via n.° 3 para vacios que van a devolverse cuando se hayan acumulado bastantes para formar un tren, etc., etc.

**75. Los patios de clasificación secundaria** se usan cuando la clasificación deseada, especialmente con respecto al orden de las estaciones, no se puede lograr en el patio principal de clasificación. Tales patios se colocan convenientemente fuera del patio de clasificación principal, y puede tener una « pendiente » para su uso. Estos patios tambien son llamados « patios de reclasificacion » o « patios de agrupacion ».

**76. Tamaño** de las vias de estos patios de clasificación. Ninguna via necesita ser mas larga que el tren mas largo que haya que preparar.

**77. Separación** de vias de patio. Recomienda la Asen Am de Ings de F. C., Manual, 1915; mínimo de centro a centro para vias maestras (vias principales de clasificación de patio) 4 a 4,20 m; via de enlace y primer cuerpo de via, 4,60 m de cualquier via adyacente. El espacio mínimo debe permitir que los hombres vean las señales y evitar que choquen con postes de luz eléctrica, etc.

**78. Recorrido de carros.** Un « corte « rara vez contiene mas de cinco carros, aun cuando mas de cinco carros esten destinados para el mismo lugar. Cada corte está (o debe estar) regulado por un guardafreno, desde la pendiente hasta cerca de su destino. El regreso de los hombres a la pendiente representa fatiga y pérdida de tiempo si caminan, y gasto si son llevados. Su transporte puede efectuarse por medio de una loco vieja ligera con un carro, o con un carro de inspección, de gasolina o eléctrico. Se ha pensado en aceras movibles.

## Patios de Entrega.

**79.** El patio de entrega se coloca fuera de los patios de clasificación. Cada una de sus vias debe ser tan larga como el tren mas largo. A menudo dos o mas trenes pueden acomodarse en una via, especialmente si se provee de enlaces. Deben proveerse tubos de aire para probar los frenos mientras se engancha la loco y el carro

del personal. *Las vias de tránsito*, por el patio ó al costado del patio, que permiten movimiento rápido y libre de locos y carros del personal; son muy necesarias y deben construirse.

### Iluminación.

**80.** La Asen Am de Ings de F. C., Manual, 1911, recomienda, para las vias de pendiente y de enlace en los patios lamparas de arco de 2.000 bujias cada una, a 9 ms o mas sobre el terreno, y separadas de 42 a 45 ms. Otras autoridades recomiendan luces de menos bujias, con menos separación. El uso de reflectores o lentes, y pantallas, etc., para dirigir la luz eficazmente requiere un estudio mas cuidadoso que el que hasta ahora se ha hecho.

**81.** Cuando el cuerpo principal de vias no esta iluminado, puede dejarse una luz detras de cada colección de carros, y correrla detras de cada nuevo « corte » que se haga.

### Estaciones de carga. *

**82. Estaciones de transbordo.** Como los patios de clasificacion sirven para preparar y distribuir los carros en los trenes, asi la estación de transbordo sirve primeramente para la distribución del contenido de los carros entre los distintos carros, transbordándolos desde un carro cualquiera a otros, sobre andenes o plataformas adyacentes a las vias en que corren los carros. Las plataformas se colocan con preferencia a nivel con el piso de los carros cubiertos, con objeto de que las carretillas puedan pasar facilmente sobre tablones colocados en el espacio entre el carro y el anden. Deben haber almacenes (cubiertos es mejor), sobre los andenes para recibir las mercancias para las cuales no haya carros dispuestos.

**83. Manipulación mecánica.** El uso de carritos eléctricos, plataformas viajeras, o transporte por cable, etc., es económico, en el transbordo y trabajo de carga, en estaciones grandes. « Donde haya que transbordar grandes cantidades de carga, se recomienda el uso de plataformas movibles con fuerza motriz y cubiertas. « (Asen de Ings de F. C. Manual de 1911, p. 401.)

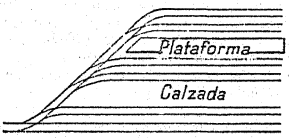

Fig. 9.

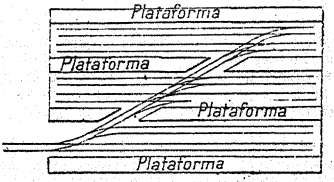

Fig. 10.

**84. Estaciones y Patios de carga.** El trazado de estas vias es simplemente el de una serie de vias paralelas, en pares, que entran en uno o mas vias de la linea principal del patio de clasificacion, con espacios suficientes entre ellas, para carretones o para andenes, como en la fig. 9; los patios son abiertos y las estaciones por lo regular cubiertas. Para economizar espacio, la via principal de tráfico, atraviesa a menudo diagonalmente el edificio, y las vias de cargar se sacan como ramales en ambas direcciones algo parecida a lo que se indica en la fig. 10. « Cuando se pueda los almacenes de recibo de carga deben tener un piso de 15 ms de ancho. Los de salida 7,50 ms. » (Asen Am de Ings de F. C.)

---

* La Asen Am de Ings de F. C. define una *terminal* como « un conjunto de facilidades provistas por un ferrocarril en un término ó en puntos intermedios de su linea con el objeto de preparar o armar y separar trenes ». Para evitar confusión no obstante, nos abstenemos de usar la palabra « Terminal » (excepto en el sentido que se indica abajo), y hemos usado « *Estación* ». Una estación que no sea una estación *de cruce* la llamamos un « Términus » (plural « Termini »), o una « Estación Terminal ».

**85. Aparatos modernos para manejar cargas.** Estos permiten economizar espacio haciendo posible construir estaciones de dos o mas pisos; un piso para recibo de carga, otro para salida, y otros para almacenaje, etc.; la carga se transfiere entre los pisos, por medio de plataformas movibles, conductores de barriles, conductores de correa, elevadores, y (para los descensos) conductos en espiral o rectos para piezas que no son frágiles, todo esto ademas de los aparatos de manejar cargas que se mencionan en el ¶ 83.

El patio de cargas debe tener una grua viajera para piezas mui pesadas; y aparatos especiales (como conductores de cubo para carbon, granos, etc.) donde haya que mover mercancias de diversas formas, pesos y condiciones.

**86. Patios para entregas por carretones.** La Asen Am Igns F. C. (Manual 1911, p. 398) recomienda vias cortas por pares de 3,60 ms de centro a centro de vias, y si es practicable, no menos de 9 ms de centro a centro de los pares; vias de no mas de 20 carros de capacidad; entrada y salida para carretones en cada extremo del camino; gruas de fuerza motriz, básculas para carretones y para la via ferrea.

## Estaciones de Pasajeros *.

**87. Generalidades.** Algunos de los puntos importantes que se deben observar en el trazado de las estaciones son : que el pasaje, equipaje y expreso se maneje tanto a la entrada como a la salida con un mínimo de atraso y confusion, y en la terminales *, sacar la loco fuera, virarla, proveerla de agua y carbón, y reengancharla al tren; tambien hacer la limpieza de carros, etc. Alguna parte de la limpieza de los carros puede hacerse en la misma estación.

**88. Plataformas.** Para hacer expedito el movimiento de pasajeros y equipaje, se recomienda por la « Comision de Patios y Terminales » de la Asen Am de Ings de F. C., marzo de 1911 que, si no se pueden proveer andenes de equipajes además de los andenes de pasajeros y al mismo nivel, el equipaje puede llevarse de un nivel a otro por medio de ascensores, colocados de tal modo que logren mantener lo mas posible el equipaje fuera de los andenes.

**89. Las rampas,** o pasajes inclinados en sustitución de las escaleras facilitan mucho el movimiento de pasajeros en las estaciones y reducen la posibilidad de accidentes en las horas de mas movimiento. La comisión de Patios y Terminales, Asen Am de Ings de F. C., marzo 1911, recomienda una pendiente que no exceda del 1 %; pero se están usando mayores pendientes con éxito. La superficie debe estar preparada para evitar el peligro de los resbalamientos.

**90. Pasillos de tránsito.** A menudo se puede hacer mucho en el trazado para reducir la congestión en la estación y en los pasajes, evitando el cruce de los pasillos de tránsito de los pasajeros para lo cual se trazan en la mayor extensión posible, paralelos entre si.

**91. Necesidades para el futuro.** Debido a las dificultades y gastos que ocasiona la reconstrucción de una estación grande cuando el tráfico llega a exceder a su capacidad, las necesidades del futuro deben calcularse para 20 años, si es posible, y de acuerdo con esto preparar el diseño de la estación.

**92. Las estaciones pequeñas y numerosas** aventajan a las estaciones grandes y únicas en las ciudades grandes. El manejo, en una sola estación de todo o casi todo el tráfico de pasajeros en una gran ciudad necesita por lo regular, un viaje largo para llegar o salir de la estación, y caminar mucho en la estación necesariamente grande en si misma para llegar a los trenes o salir; y, por eso la construcción de varias estaciones pequeñas en la misma ciudad, a lo largo de la linea ha sido sugerida (por Mr. Fred A. Delano, Pres del F. C. Wabash), aun cuando esto obligue a invertir un tiempo adicional en las paradas de los trenes expresos.

---

* Véase nota *, ¶ 81.

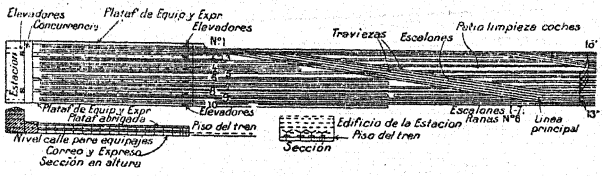

**Fig. 11.**

**93. Plan.** La fig. 11 es un trazado para una estacion terminal de pasajeros tal, como lo recomienda la comisión de la Asen Am de Ings F. C., marzo 1911; y la

**Fig. 12.**

fig. 12 tipo de cruces en la estación. En la estacion terminal, se proponen dos niveles, uno para pasajeros y otro para equipaje y expreso, junto con un sistema comprensivo de vias de enlace, con patio adyacente para limpieza de carros. Esta disposición ideal tiene por supuesto, que alterarse muchas veces debido a restricciones locales. En el plano para estación de cruces, se notará que dos vias principales se dividen en 6 permitiendo dos vias de cruce en el medio (sin desviacion en su curso), y dos vias con anden (con un anden aislado eutre ellos) a cada lado, dando asi amplias facilidades de carga y descarga, sin demorar los trenes que no tengan parada reglamentaria en la estación.

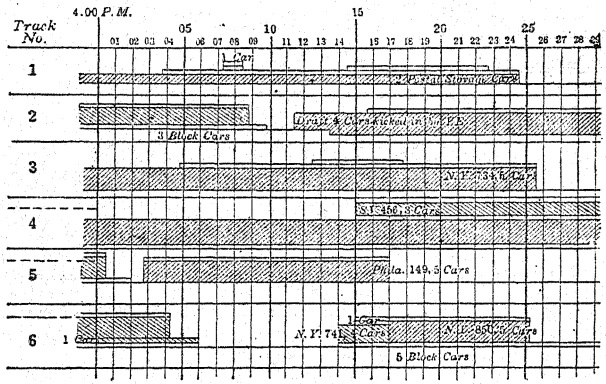

**Fig. 13.**

**94. Estudio.** La fig. 13 muestra parte de un diagrama que registra la ocupacion de varias vias del F. C. de Pennsylvania en la Estación de la calle Broad, en Philadelphia (Mr. E. B. Temple Auxiliar del Ings Jefe) durante un periodo de tiempo daoa.

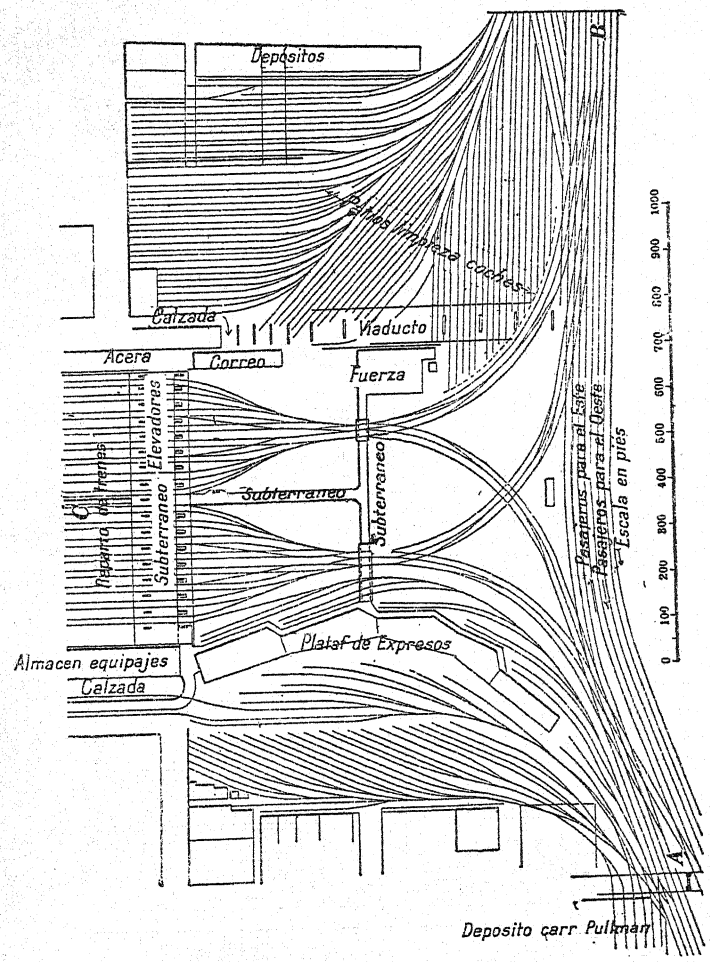

Fig. 14.

(4:00 a 4:30 p m, enero 18, 1912; solamente se enseñan 6 vias). El diagrama entero incluye 16 vias de la estación, y comprende un periodo de tiempo de las 4 a las 6 p m. Diagramas análogos mostraban las condiciones existentes durante el mismo periodo en partes del patio. Las distintas vias estan trazadas en ellos en escala vertical, de extremo a extremo. La extensión vertical, asignada a cada via representa el largo que puede ocupar sin obstruir mas de una via. Los carros y

loco están marcados con areas rectangulares. Las *dimensiones* verticales de los rectángulos representan los largos de la via ocupada por carros, etc; las *posiciones* verticales de los rectángulos representan las *posiciones* de los carros, etc., en las distintas vias; y sus *dimensiones* y posiciones horizontales representan los periodos durante los cuales las distintas vias estuvieron asi ocupadas. En la práctica, los trenes que llegan y salen se distinguen por los diversos modos de dar sombra en el dibujo a estos rectángulos; y las clases de carros y loco por iniciales, como L. C. para « locos de camino ». Diagramas análogos se han usado en los F. C. del Estado Belga en y la estación Camden del F. C. de Baltimore & Ohio.

**95**. La fig. 14, p. 1086, representa una *estación* y muestra el *retroceso* de un tren con rumbo a la estación que viniendo por *A*, sigue primero a *B*, y entonces retrocede a la estacion por ej en *C*, permitiendo asi que la loco sea rápidamente sustituida.

**96. Velocidad en el manejo de trenes.** Dicha velocidad en las terminales depende sobre todo de las facilidades realizadas para el rápido manejo de locos, pasajeros, y equipajes y para limpiar carros; tambien de la naturaleza del tráfico y de la fuerza motriz. Comparando 26 estaciones grandes de pasajeros Americanos, la Comision de Patios y Terminales, de la Asen Am de Ings de F. C. (Eng New 1911, abril 6, p. 414), encontró que el número de trenes manejados actualmente durante la hora de mas tráfico, varian de 1 a 3,5 como promedio por via (incluyendo movimiento en *todas* las vias), y desde 2 a 8 en la via de *mas tráfico;* mientras que por calculos hechos debian variar de 2 a 12. Algunas de las cifras altas fueron alcanzadas en estaciones de cruce.

**97. Operación de trenes con electricidad.** Asi se facilita mucho su rápido movimiento en las terminales, tanto mas que la fuerza motriz no necesita salir de la estación, o cambiar su posicion, para invertir la loco o el tren, o para aprovisionarse. Las vias y patios quedan de este modo en su totalidad libres para movimientos completos de trenes.

**98. Terminal de tránsito rápido.** Se disponen con frecuencia con una o mas *vias de volteo*, alrededor de las cuales los trenes pueden correr sin invertir la locomotora o el motorista. Esto es practicable a menudo con equipo de tránsito rápido, que pueda correr fácilmente en curvas agudas (fuertes) y es por tanto innecesario invertir mucho terreno para construir la via de volteo.

# ESTACIONES DE AGUA

**Las estaciones de agua** son ciertos puntos de la línea de un ferrocarril en donde las máquinas se paran á tomar agua. **La distancia de una á otra** varía (lo mismo que las estaciones ó depósitos de combustibles, que están junto de aquéllas), más ó menos, de 9 ó 10 kilómetros en las líneas de gran tráfico, á 24 ó 32 km sobre las que corren pocos trenes. Depende en mucho, sin embargo, de los lugares donde se consiga el agua. Algunas veces hay que conducirla en tubos desde 3 á 5 km ó más. El objeto de tenerlas próximas unas de otras es para evitar retardos cuando muchas máquinas están obligadas á tomar agua en la misma estación. Para evitar interrupciones en el tráfico, se colocan, á menudo, al lado de un desvío. En las estaciones se guardan grandes cantidades de agua, generalmente en tinas grandes de madera ó estanques, abrigados *en casas de estanques*. La casa del estanque se sitúa cerca de la línea, dejando solamente un espacio de .60 á 1.20 m libre para los carros.

Es de 2 pisos; se coloca el estanque en el piso superior, con su fondo de 3 á 3.60 m más ó menos, sobre carriles. En el piso bajo se halla generalmente la bomba para elevar el agua al estanque, y una estufa para impedir que el agua se congele en el invierno *.

Los estanques son generalmente de forma circular y de diámetro algunas pulgadas mayor en el fondo que en la parte superior para que se aprieten más los aros. **Su capacidad** varía generalmente de 23 á 150 m cúb (raras veces 300 m cúb ó más) según el número de máquinas que toman agua.

**El estanque de un tender** contiene de 11 á 26 m cúb; **y una máquina evapora ó gasta** de 50 á 350 lit por km, según la clase de máquina, peso del tren, pendientes, etc. Quizás 90 lit es un término medio regular para máquinas de trenes de pasajeros, y 180 para los de carga. La tabla que sigue da **la capacidad de estanques de diferentes diámetros** interiores, y profundidades de agua.

| Diámetro. | Profundidad. | Capacidad. | Diámetro. | Profundidad. | Capacidad. |
|---|---|---|---|---|---|
| Metros. | Metros cúb. | Metros. | Metros. | Metros. | Metros cúb. |
| 3.66 | 2.44 | 25.613 | 7.32 | 3.66 | 153.697 |
| 4.27 | 2.74 | 39.224 | 7.92 | 3.96 | 195.412 |
| 4.88 | 2.74 | 51.230 | 8.53 | 4.27 | 244.060 |
| 5.49 | 3.05 | 72.043 | 9.14 | 4.57 | 300.188 |
| 6.10 | 3.05 | 88.943 | 9.75 | 4.88 | 364.317 |
| 6.71 | 3.35 | 118.383 | 10.36 | 5.18 | 436.982 |

**La madera de ciprés ó de cualquier clase de pino** sirve muy bien para estanques. Las duelas pueden ser de un espesor de 6 cm para los estanques pequeños y de 10 á 12 cm para los grandes. A los fondos puede dárseles el mismo espesor. Las duelas deben acepillarse en máquinas para ajustarlas exactamente á las curvas. Entonces no es preciso interponer nada entre ellas para que cierren. Una espiga ó diente sencillo se inserta entre cada dos duelas, cerca de su parte superior, para mantenerlas en su puesto mientras se están armando. El fondo se ensambla y se coloca simplemente dentro de un canal hecho con mucha exactitud, como de 2.5 cm de profundidad, en la circunferencia interior de la tina, á algunos centímetros del fondo de las duelas.

Un estanque de 6 m de diámetro y 3.60 m de profundidad debe tener 9 aros de buen hierro, colocados algunos cms más próximos unos de otros en el fondo que en la parte superior del estanque.

El ancho de los aros 7½ cm, y el espesor de los dos más bajos de 6 mm, dismi-

* Una casa de estanque de armadura (madera) de 5.4 m en cuadro, con cimientos de mampostería para la casa y el estanque, cuesta de $400 á $600. Una de ladrillos ó mampostería cuesta algo más.

nuyendo de aquí gradualmente hasta el más alto, que tiene sólo la mitad del espesor. Los dos más bajos se colocan pegados uno al lado del otro. Estas dimensiones permiten la ejecución de los agujeros de remaches para remachar las extremidades sobrepuestas y resistir á los esfuerzos regulares que se ejercen al apretar los aros para llevarlos á su lugar *. Tres remaches de 12 mm de diámetro, colocados á 7½ cm de distancia entre sí, en línea, son suficientes para el empate de un aro inferior. Un estanque de 10.36 m de diámetro y 5.12 m de profundidad, puede tener 12 aros, los inferiores de 10 cm × 13 mm, con 3 remaches de 2 cm para la junta baja del fondo.

Los tablones del fondo deben descansar firmemente sobre sus vigas de apoyo.

Un estanque debe tener un **tubo de entrada** por el cual el agua penetra; un **tubo de desagüe** para evitar el derrame, y un **tubo de descarga** de 18 á 20 cm de diámetro en, ó cerca del fondo, por el cual pasa el agua al tender. La extremidad interior del tubo de descarga está provista de una válvula que abre el maquinista á voluntad por medio de una cuerda y una palanca exterior.

A su extremidad exterior se fija, generalmente, un tubo flexible de lona de 18 á 20 cm de diámetro, y de 2.40 á 3 m de largo, por el cual el agua entre en el depósito de agua del tender. O en lugar de una manguera puede el tubo de descarga prolongarse con un tubo metálico, suficientemente largo para que llegue hasta el tender, dispuesto de tal modo que pueda echarse hacia un lado cuando no esté en uso, ó enviarle á una posición vertical para que no estorbe á los trenes que pasan. El mismo estanque puede alimentar dos locomotoras que estén sobre diferentes vías, al mismo tiempo. Los estanques son muy durables.

**El estanque de patente á prueba de heladas de John Burnham,** Batavia, Illinois, es simplemente un estanque ordinario en el cual se impide que el agua se congele : 1.º, por medio de un techo circular que protege á un cielo raso de planchas, entre las cuales hay una capa de mortero; 2.º, por un espacio de aire obtenido por un método igual debajo de las maderas ó vigas sobre las cuales descansa el estanque. Aunque los lados están sin protección alguna, no necesitan casa, sino solamente postes y vigas fuertes sobre unos cimientos de mampostería, para sostener el estanque. Los tubos surtidores están en cajas hechas de madera y papel alquitranado.

**Los estanques se hacen frecuentemente rectangulares** con lados verticales de postes forrados con tablas y ligados en ambas direcciones por medio de barras de hierro. Son más expuestos á filtraciones que los estanques circulares. También se han hecho de hierro, pero parece que se prefieren los de madera.

**El agua para surtir los estanques** puede elevarse con bombas de mano, de vapor, fuerza animal, viento, ariete hidráulico, ó de otro modo, de un río, de un pozo hecho por una represa en un arroyo pequeño é irregular, de una cisterna ó aljibe que se halla debajo del estanque, ó de una fuente ordinaria. Muchas líneas con un tráfico de 10 á 12 trenes diarios en cada dirección, se surten de aljibes y con bombas de mano; generalmente dos hombres para una bomba.

Las líneas de un tráfico grande, cuando no se pueden surtir de agua con caída natural, generalmente emplean fuerza de vapor. **El molino de viento** ** es la fuerza más económica, y cuando está bien construído se descompone muy poco. Por supuesto, que no trabaja cuando hay calma, pero este inconveniente puede evitarse en la mayor parte de los casos, teniendo estanques suficientemente grandes que contengan agua para varios días. Sin embargo, la fuerza de vapor es la más segura.

La tabla que sigue dará una idea de **la fuerza que requiere una máquina de vapor para elevar agua.** Al encargar una máquina no se especifique el número de caballos de fuerza, sino el número de m cúb de agua que debe elevar en un número de horas dadas, á una altura y con una presión de vapor dadas (digamos de 4 á 6 kg por cm cuad). La bomba debe ser suficientemente potente para que no haya que trabajar de noche, y debe ser capaz de ejecutar por lo menos 25 por ciento más de lo que se requiere.

**Un caballo regular** puede, por término medio, elevar en 8 horas las cantidades indicadas en las primeras dos columnas, á la altura de la tercera columna, ó la suficiente para alimentar el número de locomotoras que se expresan en la cuarta columna, con cerca de 7½ m cúb para cada máquina. Dos hombres harían, más ó menos, la tercera parte de este trabajo.

---

* Un estanque como éste, armado en su lugar, cuesta $400, más ó menos.

** El costo de un molino de viento sólo para estaciones de ferrocarril varía, más ó menos, de $450 para 5.4 m de diámetro, á $1,500 para 11 m de diám. Precio en fábrica.

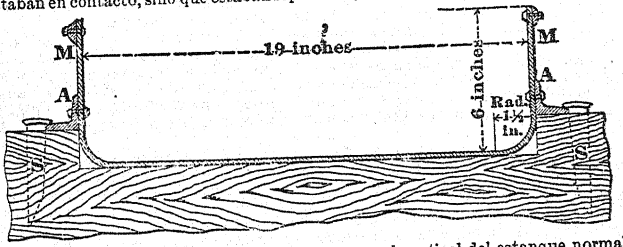
**Un estanque ó depósito de agua, con un tubo fijo de alimentación,** es preferible á una tina ó depósito ordinario con bomba cuando la localidad lo permite, por estar aquél menos expuesto á descomponerse que esta última, resultando al fin más económico. El depósito se supone que se llena entrando el agua con caída natural, y que tiene el fondo, por lo menos, á 2.40 m sobre los carriles, ó á cualquiera otra elevación que el terreno ó la altura del agua requieran. El depósito puede hacerse en el suelo, revestido con mampostería de ladrillos ó piedras y cemento, con fondo de concreto, ó construirse sobre el terreno, según la localidad. Puede tener un tubo, si se quiere, y puede estar cerca de los carriles, ó á distancia considerable, según las circunstancias *. Desde su fondo se lleva un tubo de hierro de 20 á 30 cm de diámetro (generalmente por debajo de la tierra) hasta cerca de la vía.

En este punto tiene un codo vertical y un tubo de 2.5 á 3 m de altura sobre la vía, formando un **tubo vertical de alimentación, es decir, una columna de agua,** de cuya parte superior sale el agua (por una manguera) como en el caso, del estanque. Varios de estos tubos, ó uno más grueso, pueden colocarse para alimentar dos ó más locomotoras al mismo tiempo, por sendos tubos de alimentación. En el punto en donde el tubo se dobla y se vuelve vertical, hay una válvula para abrirlo y cerrarlo, que puede actuarse por medio de una rueda de mano colocada á una altura que el maquinista pueda alcanzarla fácilmente.

En algunas de las líneas más importantes los ténderes de trenes rápidos **toman el agua á toda marcha por medio de una larga artesa ó largo acueducto ó estanque de canal,** lleno de agua, colocado entre los rieles. Estos estanques tienen generalmente 400 m de longitud. Deben, por supuesto, estar á nivel, y por consiguiente requieren que la vía esté también á nivel. Cuando se introdujeron por primera vez en Inglaterra por Ramsbottom, el estanque ó acueducto era de hierro fundido, en secciones de 1.80 m, más ó menos. Éstas se unían por medio de pernos, que pasaban por rebordes que había en sus extremidades, los cuales no estaban en contacto, sino que estaban separados por una tira de caucho vulcanizado.



Nuestra figura representa una sección transversal vertical del estanque normal. Está construído con planchas de hierro de 5 mm de espesor y 1.57 m de longitud. Las secciones están sobrepuestas 5 cm, dejando 1.52 m de longitud útil. Las planchas están cortadas un poco cónicas, de modo que la extremidad de cada sección sea 5 mm más honda que la otra, y de este modo sus partes superiores están rasas en toda su longitud. Las juntas están remachadas con una hilera doble de remaches de 10 mm, y distantes, más ó menos, 4 cm de centro á centro, y no están en

* Un depósito ó estanque sin techo de 12.25 m y 3.66 m de profundidad, revestido de ladrillos ó de mampostería, cuesta, generalmente, de $2,500 á $3,500, según las circunstancias.

direcciones opuestas uno al otro, sino alternados. En cada extremidad del estanque el fondo está doblado hacia arriba en una longitud de 1.83 m, llegando al nivel de las orillas superiores de los lados. Como se ve, las traviesas tienen un corte para alojar el estanque, el cual está sujeto á ellas flojamente por medio de dos clavos SS, colocados en cada traviesa. Las cabezas de los clavos ajustan sobre los rebordes horizontales de hierro angular de 4×4 cm AA. M y M son molduras de barras de hierro de 3×1.2 cm; los hierros angulares de los rebordes y lás molduras están en secciones de 4.5 m de longitud y remachados á los lados del estanque en toda su extensión.

El cucharón del ténder se **baja** al estanque, y se **levanta** por medio de una palanca situada en la plataforma del fogonero, y no se le deja tocar el fondo del estanque. El estanque entre carriles se surte por medio de tubos de un depósito próximo y lo regula un encargado.

Para impedir que el agua se cóngele en el invierno, se hace pasar vapor de la caldera de la bomba al estanque por tubos de hierro colocados, debajo de la tierra á lo largo en un lado de la vía. Estos tubos están provistos de ramales, que introducen el vapor en el estanque á cada 12 m de longitud. Los tubos de vapor están protegidos por cajones de madera, y provistos de válvulas para regularizar la cantidad de vapor entrante.

# COSTO DEL MOVIMIENTO DE TIERRA

**Art. 1.** Es conveniente estipular el pago de esta especie de trabajo por metros cúbicos *de excavación solamente*, en lugar de fijar precios diferentes para la excavación y el terraplén. De este modo nos desembarazamos de algunas dificultades en la cubicación, así como de las controversias y litigios, que se suscitan á menudo al determinar lo que haya de descontarse por el asiento del terraplén.

Es además nuestra opinión que, para proceder con equidad, debe emplearse la práctica inglesa de pagar los trabajadores por metro cúb y no por día. La experiencia demuestra claramente que cuando hay escasez de brazos y los jornales están subidos, apenas se puede conseguir que los hombres hagan las tres cuartas partes del trabajo que hacen cuando los salarios son bajos, y nuevos obreros están esperando ser empleados en caso de que algunos de los viejos se despidan. El autor ha palpado los resultados más satisfactorios empleando el sistema de tareas, acompañado de primas ó remuneraciones amplias para todo trabajo hecho á más de la tarea. De este modo se identifican los intereses de los obreros con los del contratista, y cada uno tiene cuidado de que los otros hagan la parte del trabajo que les corresponde.

El Sr. Ellwood Morris, I. C., de Filadelfia, fué, según creemos, la primera persona que investigó propiamente los elementos que entran en el costo del movimiento de tierra, y quien los redujo á una forma que nos facilita el cálculo del costo total, con un grado considerable de exactitud. Sus resultados se publicaron en el *Journal of the Franklin Institute* en 1841. Esta publicación forma la base sobre la cual, con algunas variaciones, consideraremos la materia; y la que usaremos tanto para el estudio del transporte en carretillas como en carretas. En todo este artículo, al hablar de una unidad cúbica, la consideraremos en su lugar antes de ser excavada para su transporte. No es necesario advertir que todo esto debe considerarse solamente como una aproximación tolerable ó término medio. Como se dijo, los trabajadores ejecutan menos trabajo, cuando los jornales están subidos, y más en el caso contrario. En gran parte depende esto, además, de la habilidad, inspección y energía del contratista y de sus encargados. Es frecuente ver dos contratistas trabajando á los mismos precios y con el mismo material, y estar uno de ellos ganando y el otro perdiendo, por falta de tacto en la distribución propia de las fuerzas, conservando los caminos en buen estado, haciendo conducir bien las carretas y carretillas, etc. Una temporada larga de tiempo lluvioso puede afectar seriamente el costo del movimiento de tierra, haciendo más difícil la aflojada, carga y descarga del material; además de mantener los caminos en mal estado para el tráfico de las carretas.

El costo total de excavar y acarrear la tierra se compone de las partidas siguientes, á saber :

1.ª *Aflojar la tierra hasta que esté en disposición de palearla.*
2.ª *Echarla en las carretillas ó carros por medio de palas.*
3.ª *Acarrearla incluyendo la descarga y el retorno de los carros.*
4.ª *Extender el material en capas sucesivas en el terraplén.*
5.ª *Mantener en buen estado el camino carretero ó la vía de tablones para los carros de mano ó carretillas.*
6.ª *El desgaste, la composición y depreciación de la herramienta y el interés sobre el costo de ella.*
7.ª *Superintendencia y aguadores.*
8.ª *Ganancia del contratista.*

Consideraremos todas estas partidas un poco detalladas, basando nuestros cálculos en la suposición de que el trabajo ordinario cuesta $1 por día de 10 horas

de labor. El resultado de nuestras tablas debe, por consiguiente, aumentarse ó disminuirse más ó menos en la misma proporción en que los jornales ordinarios aumentan ó disminuyen con relación al supuesto *.

**Art. 2. Aflojada de la tierra hasta dejarla en disposición de palearla.** Esto se hace generalmente por medio de arados ó de picos; menos costoso por medio de los primeros. Un arado de dos caballos, con dos hombres que lo manejen, á $1 por día de trabajo, $.75 por día cada caballo, y $.37 por día para el arado; incluyendo aperos, desgaste, reparaciones, etc., ó un total de $3.87, aflojará en terrenos duros ó pisados de 50 á 220 m cúbicos por día, á razón de 2.5 á 1.7 centavos por metro, ó en terreno ordinario de 300 á 450 m cúbicos, á razón de 1.26 á .83 de un centavo por m cúbico. Por consiguiente, podemos suponer comotérmino medio ordinario, que el costo real de aflojar la tierra con el arado es para el contratista el siguiente: En terreno duro y pesado, 2 cent; tierra ordinaria, 1cent; terreno arenoso, liviano, .5 cent por m cúbico: arcilla ó greda pura muy ríg da ó granzón compactado fuertemente, puede calcularse á razón de 3.25 cent; se necesitan de 3 á 4 caballos.

Con picos, el trabajo regular de un día es más ó menos de 0 á m cúb de greda dura ó granzón compacto; 19 m cúb de terreno duro y pesado; 30 m de tierra ordinaria; 45 en terreno arenoso liviano — todos medidos en el terreno mismo antes de excavar; — lo cual da, á razón de $ por día de trabaj o, para greda dura, 9 centavos; terrenos pesados, 5.2 cent; tierra ordinaria, 3.2 cent; terreno arenoso liviano, 2.16 cent por m cúbico. La arena pura no requiere sino poco trabajo para aflojarla, su costo no será más de .6 cent por m.

**Art. 3. Echada de la tierra suelta en las carretas por medio de palas.** La cantidad del material paleado por día depende en parte del peso del material, pero más de la relación que haya entre el número de picadores y de carretas al de paleadores, de modo que estos últimos nunca tengan que esperar ni las carretas ni el material. En las cuadrillas bien organizadas, los paleadores no se ocupan realmente en palear más que seis décimas partes del tiempo, estando desocupados sólo cuatro décimos de dicho tiempo, mientras que, mal organizados, pierden considerablemente más de la mitad del tiempo. Un paleador puede fácilmente echar en una carreta la cuarta parte de un m cúbico medido en su lugar (lo que es más ó menos la carga media de una carreta) de tierra arenosa en 5 minutos; de tierra ordinaria, en 6 minutos; y de cualquiera de las tierras pesadas, en 7 minutos. Esto daría, para un día de 10 horas de trabajo, 120 cargas ó como 30 m cúbicos de arena; 100 cargas ó como 25 m cúbicos de tierra ordinaria; ú 86 cargas ó 22 de las tierras pesadas. Pero de estas cantidades debemos deducir cuatro décimas partes por el tiempo perdido necesariamente; reduciendo de este modo la cantidad de trabajo efectivo á 18 m cúb de tierra liviana arenosa; á 15 m cúb de tierra ordinaria y 13 m cúb de tierra pesada.

Cuando los paleadores hacen menos que esto, es porque hay alguna desorganización en la dirección del trabajo. Suponiendo equitativas estas cantidades, tenemos que, á $1 por jornal, el costo efectivo para el contratista por palear un m cúbico de material, medido en su lugar antes de excavar, será más ó menos: en terrenos arenosos, 5.4 cent; en tierra ordinaria, 6.5 cent; tierras pesadas, arcilla, etc., 7.5 cent por m cúbico.

En la práctica, las carretas no se llenan menos de tierras pesadas que de tierra liviana. Ni hay tampoco necesidad de hacerlo, por cuanto la diferencia que existe entre el peso de una carreta y la cuarta parte de un m cúb de varias tierras es demasiado pequeña para que se tome en cuenta, especialmente si el camino se mantiene en buen estado, como lo mantendrá el contratista que conozca su propio interés. Tampoco es necesario modificar la carga por causa de las *pequeñas inclinaciones* que puedan resultar al dar las pendientes á los caminos. Una carreta de cargar tierra, por sí sola, pesa media tonelada más ó menos.

**Art. 4. Transporte de la tierra, vaciada y regreso.** Un caballo camina, por término medio, más ó menos 4 kilómetros por hora, ó 66 m por minuto; lo que equivale á 33 m de viaje en cada dirección, ó á 33 m de avance, como se acos-

* *N. de T.* — Dejamos el dólar como unidad, en todos los estudios y cálculos de costos que van á seguir, pues es una unidad monetaria muy conocida y además de muy simple relación con las que usan todos los pueblos que hablan español. Véase tabla de monedas, pág. 231.

tumbra decir en el transporte de la tierra*. Además, en cada viaje hay una pérdida como de 4 minutos que se invierten en esperar á que se cargue, en vaciar la carreta, etc. Por tanto, cada viaje durará tantos minutos cuantas porciones de 33 m haya en cada viaje, y 4 minutos más. Por consiguiente, para hallar el número de viajes por día á cualquiera distancia media de transporte, dividamos el número de minutos empleados en un día de trabajo por 4 más el número de porciones de á 33 m contenidas en la distancia total á que debe acarrearse la tierra, es decir:

$$\frac{\text{El número (600) de minutos de un día de trabajo}}{4 + \text{el número de porciones de 33 m comprendidas en la distancia de transporte}} = \text{número de viajes ó carretadas hechos por día y por carreta}$$

y como $^1/_4$ parte de m cúbico, antes de aflojarla, da por término medio una carretada, el número de cargas, dividido por 4, dará el número de m cúbicos transportados por día por cada carreta, y el gasto total de cada carreta por día, dividido por el número de m cúbicos transportados, dará el costo del transporte por m cúbico.

*Nota.* Cuando se transporte piedra suelta, que exige más tiempo para echarla en los carros, tendremos:

$$\frac{\text{Número de minutos (600) en un día de trabajo}}{6 + \text{número de porciones de 33 m comprendidas en la distancia de transporte}} = \text{número de carretadas transportadas por día y por carreta}$$

A distancias comunes de transporte, un carretero puede atender á cuatro carretas, lo cual, á $1 por día, sale á 25 centavos por carreta. Cuando los jornales están á $1, el gasto de un caballo es generalmente 75 centavos; y el de la carreta, incluyendo apero, lubricantes, reparaciones, 25 centavos; lo que da un costo total por día y por carro de $1.25.

El gasto de un caballo es el mismo en domingos y días de lluvia que cuando está trabajando, y estas consideraciones están incluídas en los 75 centavos. Algunos contratistas emplean un número mayor de carreteros, que también ayuden á cargar las carretas, de modo que el costo es más ó menos el mismo en cualquier caso.

Ejemplo: ¿Cuántos metros cúbicos de tierra ordinaria medida en el banqueo puede transportar un caballo con su carreta en un día de 10 horas de trabajo (600 minutos) á la distancia total de 330 m (á 10 porciones de á 33 m), y cuánto costará al contratista el transporte del m cúbico, suponiendo en $1.25 el costo total de carreta y caballo?

$$\text{Tendremos: } \frac{600 \text{ minutos}}{4 + 10 \text{ porciones de á } 33 \text{ m}} = \frac{600}{14} = 43 \text{ carretadas;}$$

$$\text{y } \frac{43 \text{ carretadas}}{4} = 10.75 \text{ m cúbicos;}$$

$$\text{y } \frac{125 \text{ cent}}{10.75 \text{ m cúb}} = 11.6 \text{ centavos por metro cúb.}$$

De este modo se han calculado las columnas segunda y tercera de las tablas que siguen.

**Art. 5. Colocación y arreglo de la tierra sobre el terraplén en capas regulares á nivel.** Un hombre puede extender de 38 á 76 m cúbicos de tierra ordinaria, ó de cualquiera de las tierras más pesadas ó gredas, según el estado de sequedad, etc.; esto, á razón de $1 por día, sale de 2.6 á 1.3 centavos por m cúbico; podemos calcular como término medio 2 cent el costo medio de las tierras de esta clase, mientras que $1\,^1/_2$ cent es suficiente para tierras livianas arenosas. Este gasto se evita cuando la tierra simplemente se echa en la extremidad del terraplén para vaciarla. Sin embargo, debe calcularse como $^1/_2$ cent por m cúb para mantener el lugar donde se vacía, limpio y en buen orden.

**Art. 6. Conservación del camino carretero en buenas condiciones para el tráfico de las carretas.** Los carriles ó canjilones formados por el tráfico de las ruedas y los hoyos deben siempre rellenarse; el agua de lluvia debe sacarse por medio de desagües de poca profundidad y conservarse el camino en buenas condiciones. De otro modo, el trabajo de los caballos y el desgaste de las carretas

---

* Cuando todo el material del banqueo se convierte en terraplén, la distancia media de transporte es la distancia entre los centros de gravedad del banqueo y del terraplén.

aumentará mucho. Generalmente se destina tanto por m cúbico para las reparaciones del camino, pero nosotros proponemos que sea $^1/_{10}$ de cent por m cúbico y por 33 m de dist de transporte.

**Art. 7. Desgaste, composición y depreciación de los picos y de las palas.** La experiencia ha demostrado que $^1/_3$ cent más ó menos por m cúb es suficiente para esto.

**Superintendencia y aguadores.** Estos gastos varían según las circunstancias locales; pero convenimos con el Sr. Morris que 2 cent por m cúb es, en circunstancias ordinarias, lo suficiente para cubrir los gastos á este respecto. Puede destinarse, en justicia, $^1/_3$ cent más ó menos por el trabajo extraordinario de desagües laterales, nivelación y aparejo del terraplén conforme á la pendiente, etc. En banqueos pequeños esto puede aumentarse á ½ cent por m cúbico.

**Art. 8. Utilidad del contratista.** Ésta puede en general calcularse de 6 á 15%; según la magnitud de la obra, los riesgos posibles y varias circunstancias accidentales. Fuera de esto, el contratista generalmente tiene que pagar dependientes, almaceneros y otros agentes, así como los gastos de ranchos, etc.; aunque esos gastos generalmente están resarcidos por las ganancias de los almacenes y por el precio á que pagan los trabajadores á los contratistas el alojamiento y posada.

**Art. 9 *. El conocimiento de los particulares que anteceden nos permite calcular el costo del movimiento de tierra con tolerable exactud.** Por ejemplo, tratemos de averiguar el costo por m cúb de excavación en tierra ordinaria, medida en su lugar primitivo, y de su transporte al terraplén, á una distancia media de 330 m, siendo el jornal de los trabajadores $1 por día de 10 horas de trabajo; costo de un caballo 75 cent; y de un carro 25 cent. Un carretero para 4 carretas.

| | Cent. |
|---|---|
| Tenemos costo de la aflojada ó picada de la tierra con picos, art. 2, m cúbico | 3.25 |
| Cargada de las carretas, art. 3 | 6.50 |
| Acarreo á 330 m, como se calculó anteriormente en el ejemplo del art. 4 | 11.60 |
| Su disposición en capas, art. 5 | 2.00 |
| Conservación del camino carretero, art. 6, 10 porciones á 33 m | 1.00 |
| Varias partidas mencionadas en el art. 7 | 2.60 |

| Más utilidad del contratista 10% | 2.69 |
| Costo total para la Compañía por m cúb | 29.64 |

* Hemos hecho la conversión necesaria en cada ejemplo para que resulte el costo del m cúb y no de la yarda cúb que es la unidad del texto inglés. Estas tablas y cálculos son sumamente útiles á los contratistas de obras. (*N. del T.*)

Es fácil construir una tabla como la que sigue, del costo por unidad cúbica para diferentes porciones de la distancia de acarreo. Las columnas 2 y 3 se obtienen primero por la Regla del art. 4; luego á cada cantidad de la columna 3 se agrega la cantidad *variable* de $^1/_{10}$ de centavo para cada porción de 33 m de la distancia de acarreo, para la conservación del camino, y la cantidad *constante* (para cualquiera clase de terreno dado) compuesta de los precios por yarda cúb, por picar ó aflojar, echarla en los carros, colocación en capas, bote ó desperdicios, etc., tomándolos ó de los artículos que preceden, ó modificados según circunstancias especiales. De esta manera han sido preparadas las tablas.

**Por carretas. Jornales á $1 por día de 10 horas de trabajo.**

| Distancia á que se hace el bote de tierra en metros. | Número de metros cúbicos medidos en su lugar botados por día, por cada carro. | Costo por metro cúbico, medido en su lugar por acarrear y vaciar solamente. | Tierra común. COSTO TOTAL POR METRO CÚBICO, NO INCLUÍDA LA GANANCIA DEL CONTRATISTA. | | | | Tierra dura pesada. COSTO TOTAL POR METRO CÚBICO, NO INCLUÍDA LA GANANCIA DEL CONTRATISTA. | | | |

**Art. 10. En carretillas.** El costo, empleando carretillas, puede estimarse del mismo modo que por carretas. Véase art. 1, etc. Los hombres tirando carros de mano caminan más ó menos la misma distancia durante el mismo tiempo que un caballo con carreta, es decir, 4,000 metros por hora, ó como 66 m por minuto, ó un minuto por cada 33 m de distancia.

El tiempo empleado en cargar, descargar, etc. (cuando, como se acostumbra, el trabajador llena su propio carro), es más ó menos 1.25 minutos, sin tener en cuenta la distancia de transporte; además de lo cual, el tiempo que se pierde descansando á ratos, ajustando los tablones del camino, y otras causas incidentales, equivale más ó menos á $^1/_{10}$ parte del tiempo total. De modo que, en la práctica, no debemos sino considerarle como trabajando 9 horas de las 10 de trabajo. Por consiguiente,

$$\frac{\text{El número de minutos de un día de trabajo} \times .9}{1.25 + \text{número de porciones de á 33 m comprendidos en la distancia de transporte}} = \text{el número de viajes ó cargas transportadas por día y por carro}$$

Véase la nota próxima.

El número de cargas dividido por 18½ dará el número de metros cúbicos, porque un m cúbico medido en su lugar primitivo antes de excavar, da por término medio 18½ cargas de carro de mano. Y el costo de un hombre y un carro de mano por día (digamos $1 para el hombre y 5 cent para el carro) dividido por el número de m cúb, da el costo por m cúb, de cargar, rodar y vaciar.

Ejemplo: ¿Cuántos metros cúbicos de tierra ordinaria medidos en su lugar antes de excavar, puede un hombre cargar, acarrear y vaciar, por día de 10 horas de trabajo (ó 600 minutos), siendo la distancia de transporte 330 m (ó 10 porciones de á 33 m), y cuál será el costo por metro cúb, suponiendo el jornal del hombre con su carretilla á razón de $1.05 por día?

$$\text{Tendremos}: \frac{600 \text{ minutos} \times .9}{1.25 + 10 \text{ porciones}} = \frac{540}{11.25} = 48 \text{ viajes ó cargas por día;}$$

$$\text{y } \frac{48}{18.5} = 2.6; \quad \text{y } \frac{105 \text{ centavos}}{2.6 \text{ m cúbicos}} = 40.4 \text{ cent.}$$

por m cúb de tierra echada en la carretilla, acarreada y botada y regresando con la carretilla vacía. El gasto en palas aumentaría este costo en una cantidad casi inapreciable; sin embargo, está incluído en las tablas que siguen, en el costo de la herramienta.

*Nota.* Para piedras que requieren más tiempo para cargar las carretillas, tenemos

$$\frac{\text{Número de minutos en un día de trabajo} \times .9}{1.6 + \text{número de porciones de 33 m}} = \text{número de cargas transportadas por día y por carretilla.}$$

**En carretillas. Jornales á razón de $1 por día de 10 horas de trabajo.**

| Distancia á que se hace el bote, ó á que se lleva la tierra en carretilla, en metros. | Número de metros cúbicos en su lugar cargados y acarreados, por día y por cada carretilla. | Costo por metro cúbico, medido en su lugar por carga, acarreo y vaciada. | Tierra común. Costo total por metro cúbico, no incluída la ganancia del contratista. | | | | Tierra dura pesada. Costo total por metro cúbico, no incluída la ganancia del contratista. | | | |

**Art. 12. Por medio de rastrillos* de ruedas y de tracción.** El cuerpo del rastrillo de ruedas es una caja de planchas de acero lisas, de 1.06 m en cuadro, más ó menos × 40 cm = de hondo, que contiene más ó menos 400 litros de tierra cuando se llena á nivel. La caja está abierta por delante (en algunas máquinas se cierra por medio de una compuerta cuando está llena) y puede suspenderse, bajarse y hacerse girar sobre un eje horizontal. Para llenar la caja, se baja ésta y se sostiene mientras que la pareja de caballos tira del aparato hacia adelante. Cuando está llena, se suspende más ó menos 3 dcm del suelo, y, al llegar al lugar de la descarga, se vacía volteándola sobre su eje. Todos los movimientos de la caja se ejecutan por medio de palancas y sin parar la pareja, la que, de este modo, camina constantemente. Las ruedas tienen llantas anchas para impedir que penetren en el suelo.

En el rastrillo de tracción, la caja sometida á mayor resistencia, se hace mucho más pequeña. Contiene más ó menos 115 á 190 lit, y está siempre abierta por delante. El manejo de este rastrillo* es semejante al de ruedas, con la excepción de que la caja, al estar llena, se descarga en el suelo y es arrastrada por la pareja.

Cada rastrillo * (de cualquier clase) requiere el empleo constante de una pareja de caballos y un carretero. Además se requiere en la excavación y el bote de la tierra, un número de hombres que depende de la distancia del transporte y del

* *Wheeled scrapers* (rastrillo, trailla, rastra). (*N. del T.*)

número de rastrillos. Excepto cuando sea arena ó tierra muy ligera, hay economía en emplear un arado antes de hacer uso del rastrillo.

En las distancias cortas se usan rastrillos más pequeños que en las grandes.

Nuestros cálculos están basados sobre las cargas siguientes:

| | |
|---|---|
| Para rastrillos de tracción (empleados sólo en distancias cortas) ..... | 156 litros. |
| Para rastrillos con ruedas á distancia menor de 33 m..... | 255 — |
| dist de 33 á 100 m..... | 300 — |
| — de 133 á 165 m..... | 380 — |
| — más de 165 m..... | 460 — |

El gasto diario de un rastrillo por el jornal del carretro y de la pareja de caballos es de $2.50 más ó menos. Para distancias de 130 m ó más, podemos agregar 50 centavos por día para una pareja de caballos auxiliar, para ayudar á cargar los rastrillos más grandes, que entonces se usan. Una pareja auxiliar sirve generalmente para varios rastrillos.

Debido al hecho de que las parejas están constantemente en movimiento sin descargar, caminan algo más despacio que con carretas. Calculamos 46 m por minuto (ó sean 23 m de transporte por minuto) por término medio.

Al cargar y descargar las parejas de caballos, no solamente tienen que salirse del camino, sino que también caminan más despacio que cuando están simplemente halando. Para compensar esta diferencia, haremos una adición de 33 m á cada porción de la distancia de transporte, sea corta ó larga.

Agregamos 1 centavo por m cúbico para la carga y descarga y estimamos el costo aproximado de las otras partidas como sigue:

Reparación del camino carretero $^1/_{10}$ centavo por m cúb para cada 33 m de distancia de transporte.

| Picada ó aflojada. | Tierras ligeras cent por m cúb. | Tierras pesadas cent por m cúb. |
|---|---|---|
| Por medio de p'cos..... | * | 6.5 |
| Por medio de palas..... | * | 2.6 |
| Extender..... | 1.3 | 2.0 |
| Superintendencia, desgaste, etc..... | 1.3 | 1.3 |

Repetimos que nuestros números no pueden considerarse sino como aproximaciones, y que están sujetos á grandes variaciones según la habilidad del contratista y del superintendente, resistencia de la pareja de caballos, calidad del material que ha de transportarse, estado del tiempo, etc.

$$\text{Número de viajes por día por rastrillo} = \frac{\text{Número de minutos (600) en un día de trabajo}}{\text{Número de distancias de 23 m en (dist + 33 m)}}$$

$$\text{Número de metros cúbicos medidos en su lugar antes de excavar, transportados por día por cada rastrillo} = \text{Número de viajes por día por rastrillo} \times \text{Número de metros cúbicos medidos en su lugar antes de excavar, por rastrillo y por viaje.}$$

$$\text{Costo por metro cúbico medido en su lugar antes de excavar; con carga, acarreo, vaciada y retorno} = \frac{\text{Gasto diario en una raspadora}}{\text{Número de metros cúbicos medidos en su lugar, transportados por día por cada rastrillo}} + \text{1 centavo para cargar y descargar}$$

$$\text{Costo total por metro cúbico medido en su lugar excluyendo utilidad del contratista} = \text{Costo por metro cúb medido en su lugar; carga, acarreo vaciada y retorno} + \text{.1 centavo por metro cúb en su lugar por cada 33 m de dist por reparación de camino} + \text{Costo por metro cúb medido en su lugar por la picada, extendida y botada, y superintendencia, etc.}$$

---

* Las tierras livianas las afloja el mismo rastrillo.

**Con rastrillos de ruedas.** Jornales á $1 por día de 10 horas de trabajo.

**Art. 13. Por medio de carros y locomotora** en una vía horizontal. Hemos basado nuestros cálculos sobre las suposiciones siguientes: Trenes de 10 carros conteniendo cada carro (1½ yd cúb) 1.15 m cúb medido en su lugar primitivo. Velocidad media de los trenes, incluyendo la salida y la llegada, pero ninguna parada, 16 kilómetros por hora=8 km de transporte por hora. Jornales á $1 por día de 10 horas. Aflojar ó picar la tierra, palearla, extenderla; desgaste de la herramienta, superintendencia, etc., lo mismo que con carretas, arts. 2, 3, 5 y 7. Pérdida de tiempo en cada viaje, en cargar, descargar, etc., 9 minutos=.15 hora. Por tanto, tenemos:

$$\text{Número de viajes por día y por tren} = \frac{\text{10 horas de un día de trabajo}}{.15 + \text{número de porciones de 8 km en la dist de transporte}}$$

$$\text{Número de m cúbicos medidos en su lugar primitivo por día y por tren} = \text{Número de viajes por día y por tren} \times \text{Número (10) de carros en un tren} \times \text{Número de m cúb (1.15) medidos en su lugar primitivo en cada carro}$$

$$\text{Costo por m cúb en su lugar primitivo por acarreo, descarga y retorno} = \frac{\text{Gastos del tren en un día} + \text{costo de la vía en un día}}{\text{Número de m cúb medidos en su lugar primitivo y por tren}}$$

**Gastos del tren en un día :**

| | |
|---|---|
| Precio de 10 carros á $100 | $1,000 |
| Precio de locomotora | 3,000 |
| | $4,000 |

| | |
|---|---|
| Intereses de un día al 6% sobre el precio del tren | $ .67 |
| Pago del maquinista, que también es fogonero | 2 |
| Caporal para la descarga | 2 |
| 3 hombres para descargar | 3 |
| Combustible | 2 |
| Agua | 1 |
| Reparación de locomotora y carros | 2.33 |
| Gasto diario total de un tren | $ 13 |

Depreciación (considerando la duración de material rodante, 10 años)
dígase $100 por año por $1,000
= $400 — tren
= $ 4 por día (suponiendo 100 de labor por año). 4
Gasto diario y depreciación de un tren ..... $17

Suponiendo el costo de la vía puesta á razón de $2,500 por milla, y su duración de 5 años, **el gasto diario de la vía**, con intereses, depreciación, manejo y reparaciones, se puede calcular en $6 por cada milla (1.609 m) de transporte.

Por consiguiente,

$$\text{Costo por m cúb, medido antes de excavarlo transporte, botada y vuelta} = \frac{\$17 + (\$6 \text{ por milla de transporte (como \$4 por km)})}{\text{Número de viajes por día y por tren} \times \text{Número de carros por tren (10)} \times \text{Número de m cúb en cada carro (1.15)}}$$

$$\text{Costo total por m cúb medido en su lugar primitivo, sin contar utilidad del contratista} = \text{Costo por m cúb (medido en su lugar) del acarreo, descarga y retorno} + \text{Costo por m cúb (medido en su lugar), por aflojar, ó picar, extender ó botar, y superintendencia, etc. (Arts. 2, 3, 5 y 7.)}$$

**Por medio de carros y locomotoras.** Jornal $1 por día de 10 horas.

Cuando se ejecutan obras en grande escala, el **excavador de vapor, draga de tierra ó pala de vapor** economiza generalmente tiempo y dinero. Cuando la altura del banqueo es menos de 3 m, se pierde tanto tiempo mudando el excavador de un lugar á otro, que no se puede usar con ventaja. En terrenos duros pueden hacerse banqueos de más ó menos 5 á 6 m de altura sin cambiar el nivel de la máquina. Para alturas mayores en terrenos como éstos, el trabajo se hace á dos niveles, porque el cubo ó sacador no alcanza á más altura. Pero en arena y granzón suelto pueden hacerse banqueos mucho más altos á un solo nivel.

El excavador se parece á una draga en su apariencia y en el modo de operar. Un cubo grande de planchas de acero, semejante al de la draga, con un fondo chato de charnelas y provisto de dientes de acero cortantes, penetra en la tierra arrastrado por debajo de ella, con fuerza de vapor. La descarga del material se hace por el fondo movedizo del cubo, sobre carros que lo transportan á otra parte, ó lo botan.

Cada máquina está montada sobre un carro de vía normal, que puede engancharse á un tren ordinario de carga. El carro se hace de hierro ó de madera, y está provisto de un accesorio de locomotora, por medio del cual puede ser movido de un punto á otro, según avanza el trabajo. Estas máquinas también pueden usarse como **carro auxiliar** ó **carro de grúa ó aparejo**. Cada máquina tiene un estanque de agua (que contiene de 1,100 á 2,000 lit), para alimentar su caldera. Antes de principiar la excavación, la punta del carro más próxima á la obra se levanta sobre la vía por medio de gatos hidráulicos ó de tornillos, sobre los cuales descansa durante el trabajo.

En los terrenos duros el excavador deja los lados de la cortada casi verticales y el talud deseado se hace después con picos y palas. Cuando el suelo es duro ó está muy helado, puede aflojarse antes de excavarlo por medio de explosivos.

El excavador tiene que mudarse hacia adelante (á medida que la obra avance) 2.40 m más ó menos á la vez. Como generalmente se hace, puede excavar á una distancia de 5 m horizontalmente desde el centro del carro, en cualquiera dirección, y puede vaciarse á 3.6 m sobre la vía. En arena ó granzón, la máquina saca por minuto durante la excavación efectiva 3 cubos llenos (de 3½ á 4½ m cúb el cubo, =2.80 á 3.80 m cúb en su lugar); en greda dura 2 cubos rasos por minuto (=2.2 á 3 m cúb en el cubo y 1.9 á 2.5 m cúb en su lugar). El trabajo medio de un día (10 horas) de una máquina « N.º 1 » es 380 m cúb más ó menos en tierra dura, y de 912 á 1,140 m cúb en arena ó granzón. En esta cantidad están incluídas las dilaciones inevitables y ordinarias para tener listos los carros para el excavador.

Los excavadores usan más ó menos de 5 á 6 atmósferas de presión, queman de 46 á 70 kg de carbón y requieren un maquinista, un fogonero, un hombre para atender á la grúa y de 5 á 10 trabajadores, incluyendo el capataz. Los trabajadores atienden á los gatos, colocan la vía para el excavador y los carros de descarga, ayudan á mover estos últimos, traen ó bombean el agua, etc.

Después de llegar al lugar del trabajo, se necesitan más ó menos 30 minutos para poner el excavador en condición de trabajar y un tiempo igual después de terminar el trabajo, para ponerlo en estado de transportarlo.

Los números que siguen se han tomado de los datos sacados de un trabajo hecho por una máquina « N.º 1 », desde mayo hasta noviembre de 1883. El material era greda dura con depósitos de arena. Los gastos hechos por día de trabajo de 12 horas á razón de $1.50 por día de dicho trabajo, fueron :

| | | |
|---|---|---|
| Agua suministrada sin restricción alguna | $ 5 | |
| Carbón bituminoso, 1½ tonel | 10 | |
| Salario del maquinista | 4 | |
| — de un fogonero | 1.50 | |
| — de un peón para atender á la grúa y la excavadora | 2.50 | |
| — de un capataz | 3 | |
| — de 8 trabajadores á $1.50 | 12 | |
| Aceite, desgastes, reparaciones (estimados) | 5 | |
| Interés sobre el costo de la máquina ($7.500) | 1.25 | |
| | $44.25 | |

Reduciendo esto á nuestro jornal tomado por modelo, de $1 por día de 10 horas esta suma daría más ó menos $30.

Reducida al mismo modelo, teniendo en cuenta la pérdida de tiempo, relativamente mayor al principiar en la mañana y parar en la tarde, la cantidad media excavada por día, medida en su lugar ó antes de excavada, fué, en banqueos de poca altura, de 403 m cúb; en banqueos profundos, 912 m cúb; término medio de toda la operación, 608 m cúb.

Esto daría como costo de la aflojada y echada á los carros del m cúb medido en su lugar ó antes de excavado, 7.4 centavos, 3.3 centavos y 4.9 centavos respectivamente; mientras que su costo por ararla y palearla, en terreno duro y pesado, es más ó menos, según los arts. 2 y 3, de 9.6 centavos, y picando y paleando como 13 cent.

**Art. 14. Transporte de piedra de excavación por medio de carretilla.** Un metro cúbico de piedra dura, medida en su lugar primitivo, ó antes de ser volada, pesa más ó menos 2.3 toneladas si es piedra arenisca ó roca conglomerada, ó 2.6 toneladas si es granito bueno compacto, gneis ó piedra caliza. De modo que es suficiente aproximación en la práctica para nuestro caso, tomar el peso de cualquiera de ellos, á razón de 2.3 toneladas por m cúb más ó menos, medida en su lugar ó sea antes de volarla.

Ahora bien, **un metro cúbico sólido, convertido en pedazos** por medio de explosivos, para su transporte en carretillas ó carretas, ocupará más ó menos un volumen de 1.8 ó $1^1/_5$ m cúb; mientras que la tierra ordinaria, después de aflojada, no aumenta sino á 1.2 ó $1^1/_5$ de su volumen primitivo, aunque después de empleada en terraplenes, se reduce á menos de su primitivo volumen. Al hacer el presupuesto para el transporte de tierra, se supone que $^1/_{18}$ parte de m cúbico medida en su lugar ó antes de excavada, es carga regular para una carretilla. Un metro cúbico de dicha tierra, medida antes de ser aflojada, pesa por término medio 1.42 toneladas, por consiguiente : $\frac{1,420}{18} = 79$ kg es el peso de una carga de carretilla, ó 65 lit de tierra floja. Calculando que una carretilla de piedra suelta pesa más ó menos lo mismo que una de tierra, podemos tomarla por $^1/_{32}$ de metro cúbico, lo que da $\frac{2,300 \text{ kg}}{32} = 72$ kg por carga de piedra suelta que ocupa un espacio de 57 lit.

En la tabla que sigue, las columnas 2 y 3 se hicieron siguiendo el mismo principio que las hechas para el cálculo de transporte de tierra, como se indicó en el art. 10. La columna 4 se prepara agregando á cada cantidad de la columna 3, .2 centavo por cada 33 m más ó menos de dist de transporte, por conservación de los tablones del camino, etc., como 58 cent por m cúb medido antes de excavar, como costo efectivo por aflojar, incluyendo herramienta, taladros, explosivos, etc., lo mismo que un desagüe moderado, y cualquiera otra contingencia ordinaria, no incluída en la columna 3. Las utilidades del contratista no están por supuesto incluídas.

Amplias experiencias demuestran que con jornales de á $1, los 58 centavos asignados anteriormente por m cúb son un precio bastante suficiente por aflojar roca dura en circunstancias ordinarias. En la práctica, el costo es generalmente de 39 á 78 centavos según la posición de las capas, su dureza, tenacidad, agua y otras consideraciones. La arcilla esquistosa blanda y otras rocas semejantes, pueden muchas veces extraerse por medio del pico ó del arado, á un costo tan bajo como de 20 á 26 centavos, mientras que, por otra parte, desmontes de poca altura, en roca muy tenaz, con las capas en una posición desfavorable, especialmente en el fondo de una excavación, pueden costar $1.3 por m, y aun considerablemente más. Estos, sin embargo, son casos excepcionales, que relativamente se presentan rara vez.

Para volar roca dura ordinaria, se requiere más ó menos de 112 á 180 gramos de pólvora por m cúb medido en su lugar, antes de excavar, pero la naturaleza de la roca, la posición de las capas, etc., pueden aumentarla hasta 225 gr ó más.

La roca blanda necesita á menudo más pólvora que la dura. Un hombre práctico en el manejo de la chompa puede perforar por día de 2.4 á 3 metros de profundidad haciendo taladros de 75 cm de hondo, más ó menos, y de 5 cm de diámetro, en roca dura ordinaria y á razón de 49 á 60 centavos por metro. Los perforadores reciben jornales mayores que los trabajadores ordinarios.

**Transporte de piedra dura en carretillas.**

Jornales á $1 por día de 10 horas de trabajo.

**Art. 15. Transporte de piedra, de excavación, en carretas.** Una carretada de piedra puede calcularse en $^1/_6$ m cúbico medido en su lugar, antes de ser volada. Pesará por término medio 383 kg, ó solamente como 18 kg más que una carretada de tierra ordinaria. Como la carreta misma pesa más ó menos ½ tonelada, el peso total es más ó menos igual en ambos casos. Las columnas 2 y 3 de la tabla que sigue se calcularon bajo el mismo principio que para el transporte de tierra, como se indicó en el art. 4. La columna 4 se preparó agregando á la columna 3 las partidas siguientes :

Por volar la piedra (y por todo con excepción de las partidas de la columna 3. carga y conservación del camino carretero), 58 centavos por metro cúbico medido en su lugar, antes de volarla; y por reparaciones del camino, $^1/_3$ de centavo por cada 3 m de bote, no incluída la utilidad del contratista.

**Piedra ó roca suelta** costará como 39 centavos menos por metro cúbico, y aun la roca *sólida* costará por término medio 13 centavos menos de lo que indican las tablas.

**Art. 16. Transporte de piedra (excavada) en carros y locomotoras,** por una vía á nivel. Nuestros cálculos están basados en las suposiciones siguientes: Un tren de 10 carros que contenga cada uno $^3/_4$ m cúb de roca (medido en su sitio). Velocidad media del tren incluyendo paradas, salidas, llegadas, etc., pero no dilaciones: 16 kilómetros por hora. Aflojada de la piedra, 58 centavos (en su sitio)

Para cargar la piedra en las carretas, 10½ centavos por metro cúbico medido antes de volada. Velocidad media del tren, incluyendo salida y llegada, pero no paradas, 16 kilómetros por hora=5 millas de transporte por hora.

Aflojar la roca, 58 centavos por m cúbico, medido en su lugar. Costo de la vía, por intereses y conservación, $3 por día y por milla (1,609 m) de distancia de transporte. Los cálculos se han hecho bajo el mismo principio que los del art. 13.

# TÚNELES

Los túneles para ferrocarriles deben ser, **si es posible, rectos**, especialmente en los de una sola vía, por cuanto las colisiones ú otros accidentes que ocurren en un túnel son esencialmente desastrosos. Raras veces es conveniente hacer un túnel en tanto que la cortada no excede de una altura de 18 m. La roca firme de una dureza mediana y naturaleza durable **es el material más favorable para túneles**, especialmente si está libre de manantiales y si las capas están dispuestas horizontalmente. En la roca blanda ó esquistosa (aunque dura y firme al principio) ó en tierra, se hace necesario dotarlos de un revestimiento de ladrillos ó piedras con cemento. Un túnel debe tener una **pendiente ó inclinación** en una dirección, para facilitar más tarde el desagüe y la ventilación. No se requiere una disposición especial para la **ventilación** durante la construcción ó después de ella, cuando la longitud del túnel no excede de 300 m; pero excediendo de esta longitud, se recurre generalmente durante la construcción á pozos ó respiraderos, ó se proveen de los medios para introducir aire por tubos desde sus bocas. Pero después de concluída la obra, excepto en circunstancias especiales, nada de esto se necesita. Los pozos respiraderos á menudo arrastran el aire hacia adentro, y frecuentemente, aun ayudados por una pendiente escarpada y uniforme, no aseguran la ventilación. El túnel del Monte Cenis, debajo de los Alpes, concluído en 1871, tiene 12 kilómetros de longitud y no tiene respiraderos, aunque tiene pendientes en subida en cada extremidad, que es lo más desfavorable para la ventilación sin respiraderos.

Fué hecho así para facilitar el desagüe. Su ventilación se mantiene haciendo entrar el aire por las extremidades por medio artificial. El túnel de Hoosac, en Mass., de 7,200 m de longitud, tiene respiraderos, uno de ellos de 314 m de profundidad, pero fueron hechos para facilitar el trabajo. **Los respiraderos cuestan generalmente** de 1½ hasta 3 veces más el m cúbico que el túnel mismo, debido á la mayor dificultad para excavar, extraer el material y deshacerse del agua; todo lo cual se hace izando el material. Cuando los respiraderos se hacen en tierra, deben revestirse lo mismo que los túneles, y este revestimiento requiere generalmente que se apuntale por debajo. O bien puede construirse dicho revestimiento sobre el respiradero en ejecución, y después hacerse descender aquél minando por debajo gradualmente. El área de la sección varía generalmente de 4 á 9 metros cuadrados. Tienen la gran ventaja de acelerar la obra, aumentando el número de puntos donde puede trabajarse; pero si se colocan demasiado próximos unos á otros, su costo perjudica. El aire en algunos túneles, durante la construcción, se vicia más que en otros, de modo que, después de comenzado el trabajo, es conveniente establecer respiraderos de aire comprimido, cuando no se hayan hecho con anticipación. Al excavar el túnel mismo, se hace una galería ó pasaje de 1.5 á 2.4 m de altura y de 1 á 3.6 m de ancho, como avance ó adelanto, y se mantiene siempre á una distancia corta (de 3 á 30 m ó más, según la firmeza del material) delante de la obra. En túneles abiertos en roca, la galería se hace justamente debajo de la parte superior del túnel, de modo que los trabajadores puedan hacer las perforaciones en el fondo para volar la roca; pero en tierra la galería se hace en el fondo ó piso del túnel, como más conveniente para agrandar la abertura hasta el tamaño del túnel, minando por debajo y dejando caer la tierra. Cuando se hacen túneles en tierra, el techo y los lados de la galería como los del túnel deben estar sujetos, para que no se puedan hundir antes de la construcción del revestimiento, y esto se hace por medio de hileras de puntales verticales de madera y dinteles ó durmientes horizontales, entre los cuales y la tierra se colocan pedazos de tablas ordinarias para formarle techo y soportes laterales provisionales á la excavación. Los puntales y dinteles se colocan primero, y después se meten entre ellos y las caras de la excavación las tablas á fuerza de golpes de martillo. Esto se va quitando gradualmente á medida que progresa el revestimiento. Este **revestimiento**, cuando se hace de ladrillos, se ejecuta generalmente del espesor de 2 ó 3 ladrillos (40 á 50 cm), en el pie, y de 1½ á 2½ ladrillos de espesor en la parte superior, y cuando se hace de piedra bruta con cemento, se le da la mitad más de grueso. Es importante que los ladrillos ó piedras sean de una calidad excelente y dura y asentados en buen cemento. Los ladrillos deben hacerse de la forma del arco. A medida que se termina el resvestimiento por partes, y antes de quitar las cimbras, debe rellenarse completamente

y con cuidado **cualquier cavidad ó vacío** que haya entre el revestimiento y la tierra. Aun en roca se hace necesario el revestimiento si aquélla no es de naturaleza durable, como el esquisto ordinario, ó si tiene grietas. **La sección transversal** de un túnel para una sola vía, hecha en cualquier punto para carros de un ancho extremo de 3.30 m, no debe ser menor de 4.5 m más ó menos, por 5.4 m de alto; ni, en una vía doble, menos de 8 m de ancho por 7.4 m de altura; á menos que en último caso el material sea roca dura, en el cual no se requiere un arco alto para revestirlo. El techo puede entonces ser mucho más rebajado, de modo que la altura de 6 m es suficiente. Para carros de un ancho total de 3 m, el ancho del túnel puede reducirse á 7.5 m; para carros de 2.7 m de ancho, á 6.9 m. Muchos se han construído de 6.6 m solamente. El túnel del Monte Cenis es de 7.9 m de ancho por 7.60 m alto. **La relación de la marcha ó progreso diario** desde cada boca de un túnel, varía de .45 á 2.70 m de longitud en 24 horas, relevándose los trabajadores 3 veces. En el túnel del Monte Cenis, las cantidades extremas del avance ó progreso de la obra fueron más ó menos de 1.2 á 2.7 m por día durante un año entero y de cada lado del túnel. Se emplearon en la ejecución de las galerías taladros actuados por aire comprimido, teniendo dichas galerías 3.6 m de ancho por 2.40 m de alto. Ordinariamente pueden tomarse de .45 á 1 m como término medio. La diferencia de la proporción del progreso ó avance en la construcción, entre un túnel de una sola vía y uno de vía doble, no es grande como podría suponerse; por cuanto en un túnel ancho se pueden emplear más y mejor las fuerzas que en uno angosto. Cuando el túnel se construye en tierra, la construcción del revestimiento iguala más ó menos al tiempo empleado para la excavación de uno en roca. Si se hace en roca, con jornales á $1, **el costo** varía ordinariamente con la naturaleza de la roca, de $2.6 á $6.5 por metro cúbico en el túnel mismo, y de $3.9 á $13 en las galerías, mientras que los respiraderos cuestan generalmente un 50% más que las galerías. El costo de un túnel de una sola vía, cuando los jornales están á razón de $1 por día, es generalmente de $100 á $246 por metro de longitud. Sin embargo, los trabajos de un túnel están expuestos á serias contingencias que no pueden preverse. Como el techo y las paredes del túnel quedan imperfectos después de volada la roca, deben calcularse la altura y el ancho para el contratista como de .45 á .60 m mayores que el espacio neto establecido. De cualquiera manera, el modo de medir ó cubicar debe expresarse claramente en las estipulaciones del trabajo. Cuando se construye un túnel con una pendiente uniforme, el trabajo progresa en general más satisfactoriamente en la extremidad más baja, porque el descenso favorece la salida de las aguas de manantial, que generalmente se encuentran; mientras que en la boca superior dicha agua debe sacarse por medio de baldes ó bombas. La boca superior tiene, sin embargo, la ventaja de desembarazarse más pronto del humo que resulta de los barrenos. Antes de principiar un túnel, y aun antes de resolverse á hacerlo, deben practicarse **pozos ó excavaciones de prueba**, para cerciorarse de la naturaleza del material. En los túneles largos es necesario tener el mayor cuidado y exactitud en conservar la línea de dirección, á fin de que el trabajo que se ejecuta por ambas bocas se encuentre precisamente en el centro.

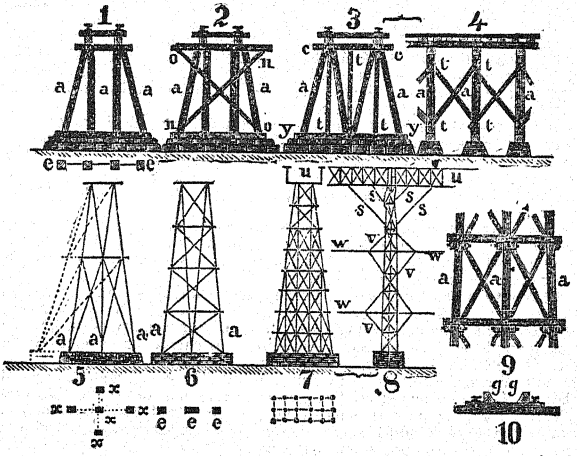
En la galería del túnel de Vosburg (Pensilvania) del ferrocarril de Lehigh Valley, construído en 1884 con una sección transversal de 2.29×7.9 m, el **progreso medio** por día de 24 horas con dos remudas de á 12 horas cada una, fué como sigue: taladrando á mano, .84 m á .72 m respectivamente en cada extremo; con taladros demáquina (dos taladros rivales en competencia), 1.7 á 2.40 m. El material consistía en piedra arenisca aplomada dura. Para todo el túnel, el progreso fué de .60 m más ó menos por día.

Para más informes respecto á túneles, recúrrase al tratado muy amplio sobre la materia del Sr. H. S. Drinker, publicado por los Sres. Wiley.

# PILAS

## (CABALLETTES, TORRES, etc.)

Las figs. 1, 2, 3, 5, 6, 7, son **elevaciones de pilas**, vistos á través de la vía ó camino. Podemos considerar la fig. 1 como adaptada á una altura de 3 á 6 m más ó menos; las figs. 2 y 3, á alturas de 6 á 9 m; la fig. 5, de 9 á 12 m; la fig. 6, de 12 á 18 m aproximadamente. Estas armazones por supuesto admiten muchas modificaciones. Están generalmente apoyadas en mampostería, como se representa en las figuras, y así se evita á las maderas inferiores el contacto con la tierra, que produce más pronto su destrucción. Es conveniente hacer estas bases suficientemente altas para impedir que las bestias y vehículos que pasen las destruyan. Hasta la altura de 12 á 15 m más ó menos, es suficiente una sola hilera de



postes ó puntales, *a*, *a*, *a*, figs. 1 á 9, como se indica en *ee*, debajo de las fig. 1 y 6; pero cuando aumenta la altura, deben introducirse más puntales, como se ve en *x*, *x* debajo de la fig. 5; ó dos hileras completas, ó tres hileras, como se indica debajo de la fig. 7 y también en la fig. 8, que es una vista lateral de la fig. 7. Las figs. 7, y 8 se parecen mucho á los caballetes de 58 m de altura, con bases de mampostería de 9 m de alto (S. Seymour, I. C.) que sostenían el ferrocarril de Erie (ahora el ferrocarril de Nueva York, Erie, etc.) sobre **el río Genesee, en Portage, N. Y.** En dicho puente cada pila tenía 21 puntales de 35 cm en cuadro en su base, y 15 postes de 30 × 30 cm en su parte superior. Las otras maderas eran de 15 × 30 cm, muchas de ellas en pares abrazando los postes. Este viaducto de una sola vía se principió el 1.º de julio de 1851 y se concluyó el 14 de agosto de 1852. Contenía 3,790 metros cúb de madera y 49 toneladas de hierro. En sus cimientos había 7,000 m cúb de mampostería. Su costo total fué de $140,000 más ó menos. Se quemó en 1875, y fué reemplazado, en menos de tres meses. por un **viaducto de pilas armadas de hierro** para una sola vía que contenía por todo 603 tons de hierro y 309 metros cúbs de madera; costando por todo, exceptuada la mampostería, $95,000 más ó menos. A menudo se colocan los postes de las pilas en pares; y las otras maderas pasan por entre ellos, todo asegurado con pernos.

En la fig. 4 los postes *a*, *a*, *a*, son vistas de extremo de los tres postes, seme-

jantes al de la fig. 3, y *tt*, son brazos diagonales que se prolongan de un poste á otro. Pueden colocarse ó en el intermedio de los puntales, como en la fig. 3, con las cabezas de los dos exteriores terminando en el dintel, *cc*, de una pila, y sus pies fijos al durmiente, *yy*, del que sigue; ó todos ellos pueden clavarse ó asegurarse por medio de pernos á los puntales mismos, como en la fig. 4. Esto último es lo mejor, porque sirve además para reformar los puntales, como lo hacen también las crucetas *oo*, *nn*, fig. 2; pero éstas se omiten á menudo. Durante el pasaje de un tren, la presión del vapor hacia atrás, ejercido por medio de las ruedas motrices contra la vía, produce un empuje serio en el sentido de la vía, que tiende á volcar las pilas, y la aplicación repentina de los frenos á un tren en marcha produce un esfuerzo ó empuje semejante en la dirección opuesta. Estos esfuerzos son más peligrosos con el aumento de altura de las pilas ó caballetes. Ordinariamente los puntales exteriores pueden tener una inclinación de 12 á 20 por ciento.

Los puntales ó postes no deben tener menos de 30 cm en cuadro, excepto en pilas muy bajas, y aun entonces no menos de 25 × 25 más ó menos. Las diagonales pueden ser tan anchas como los postes y más ó menos de la mitad de su espesor. La distancia de una pila á otra, cuando la calzada está sostenida simplemente por vigas longitudinales, no debe exceder de 3 á 3.6 m en los viaductos para ferrocarriles; pero si estas vigas están soportadas también por tornapuntas por debajo, como *ss*, en la fig. 8, ó por tirantes armados de hierro, puede aumentarse la distancia á 4.5, 6 ó más metros. Pero cuando las pilas son muy altas, y contienen una gran cantidad de madera, es más económico ponerlos más distantes unos de otros, digamos de 9 á 18 metros; y apoyar el ferrocarril sobre vigas armadas regulares como en *uu*, fig. 7 y 8, como en un puente con pilas de mampostería. En el viaducto de Genesee, las pilas armadas estaban colocadas á una distancia de 15 m de centro á centro.

Cuando estos caballetes, como el de la fig. 8, son demasiado delgados en proporción de su altura, se puede aumentar su estabilidad agregándoles vigas *ww* que pasan de una á otra; y aún más, poniéndoles refuerzos diagonales *vv*, como en el antiguo viaducto de Genesee.

Arréglense las piezas, en los posible, para que se puedan cambiar por nuevas al deteriorarse.

**En las curvas** se debe aumentar la resistencia hacia el lado convexo, como lo indican las líneas de puntos en la fig. 5. En las pilas muy altas especialmente (así como en los puentes) no se deben omitir jamás las guardarruedas, tanto al interior como al exterior de los carriles.

**En terrenos pantanosos**, se pueden hacer estacadas para sostener las pilas, ó dejarse fuera del suelo para que ellas mismas formen los postes. Estas pilas se pueden emplear á menudo ventajosamente, aun cuando después queden cubiertas por los terraplenes. De esta manera sostienen los carriles en su propio nivel hasta que el terraplén ha alcanzado su asiento final.

Se emplean generalmente para evitar los gastos de terraplén, especialmente cuando la tierra se encuentra lejos. Aun cuando es tan conveniente la tierra como la madera, rara vez cuestan más de la mitad que los terraplenes, hasta con una altura de 9 m. Pero debido á su fácil deterioro deben emplearse tan sólo en casos de necesidad, ó como expediente provisional.

# MATERIAL RODANTE

## GENERALIDADES

**1. Características generales** y detalles comunes a ambos, locomotoras y carros. Bajo esta denominacion tratamos de dar solamente una información general tal, que pueda ser útil a los ingenieros *civiles* a quienes interesa sobretodo la planta *fija* de los ferrocarriles.

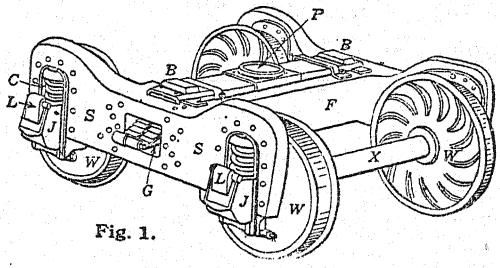


Fig. 1.

**2. Carretillas.** Una carretilla, fig. 1, es un marco en el cual están colocadas las cajas de las chumaceras, *C*, de los ejes y que soportan el cuerpo del carro. En los E. U., se hace rara vez que la carretilla soporte el vehículo directamente, de modo rígido, sino que casi siempre está conectada al carro o locomotora por medio de un pivote, *P*, que permite un juego para adaptarse a los cambios en la direccion de la via. Las piezas laterales, *S S*, de la carretilla, se hacian anteriormente armadas de fuertes planchuelas de acero, formando una armadura simple; hay todavia muchas en uso. En equipos mas recientes se usan con frecuencia armaduras de acero prensado (que actúan como vigas) y también armaduras de acero fundido, cuya plantilla está hecha por las antiguas armaduras de planchuelas.

**3. El pivote,** *P*, está en el centro de la carretilla, excepto en tipos especiales de carretillas de locomotoras, y en algunas carretillas de carros eléctricos donde se usa un solo motor y un par de ruedas y donde el pivote se coloca casi cerca de las voladoras, para darle mas « adhesion ».

**4. Soportes laterales.** La carga es generalmente soportada por platos en el pivote, y solamente las cargas debido al movimiento del carro son soportadas por las placas, *B, B;* pero en algunos tipos que se usan ahora, todas las cargas son soportadas por los laterales, mientras que el pivote no soporta ninguna.

**5. Muelles.** Se colocan elípticos, planos, o espirales, entre el marco principal, *F*, y el puente, *B P B*, que soporta el plato del pivote. Para carros de pasajeros, se coloca cuando menos un muelle espiral entre cada caja de chumacera y el marco de la carretilla. Los muelles espirales se hacen en mazos de dos o más, uno dentro del otro, y estos mazos se usan tambien en pares, lado a lado, o en grupos de cuatro o más, especialmente cuando se usan entre el marco de la carretilla y el cuerpo del carro. Los muelles semi-elípticos se usan en locomotoras.

**6. Cajas de Chumaceras.** Los muñones giran en las cajas de chumacera. El asiento se hace por su puesto sobre la parte superior del muñon. Cada caja debe ser bastante grande para contener un aprovisionamiento de estopa engrasada para lubricacion. Una tapa, *L*, permite el acceso, y evita mucho la entrada de la basura. Las chumaceras de rodillos se han usado en la tracción eléctrica.

**7. Muñones.** Los muñones están en los extremos de los ejes, fuera de las ruedas en las carretillas de arrastre de dos ruedas de las locos; en los ejes de las voladoras de las locos, están entre las ruedas voladoras. Los muñones varian 3 $^3/_4$ a 6 plgs (95 á 152 mm,) en diam y de 7 á 11 pulgs (178 á 279 mm.) en largo. Los muñones de carretillas de arrastre son hasta de 8 × 14 pulgs (203 á 356 mm.).

## Ruedas.

**8. Materiales.** Las ruedas de hierro fundido en las que la llanta y la pestaña han sido enfriadas para aumentar la dureza de la superficie, se usan todavia mucho en el servicio de carga; las de acero ensunchadas, casi se usan exclusivamente en el servicio pesado de pasajeros.

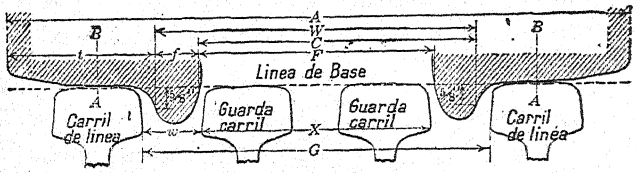

**Fig. 2.**

**9. Llanta y pestaña.** La fig. 2 muestra las ruedas de hierro fundido tipicas de los maestros constructores de carros, en relacion con la cabeza del carril, incluyendo los guardacarriles como en fig. 2.

$A$ = cartabón total = 5'4 $^{3}/_{8}$" (1,635 m);
$C$ = cartabón de comprobación = 4'6 $^{29}/_{32}$"; (1,382 m);
$f$ = grueso de pestañas = 0'1 $^{15}/_{32}$" (0,031 m);
$X$ = cartabón de guardacarril = 4'5" (1,346 m);
$G$ = cartabón de vía = 4'8 $^{1}/_{2}$" (1,435 m);
$W$ = cartabón de rueda = 4'7 $^{11}/_{16}$" (1,413 m);
$F$ = cartabón de pestaña = 4'5 $^{7}/_{32}$" (1,351 m);
$t$ = llanta = 0'4 $^{11}/_{32}$" (0,110 m);
$w$ = vía de pestaña = 0'1 $^{3}/_{4}$" (0,044 m);

El diámetro de la rueda se mide en la linea de centro, $A$ $B$, del carril.

**10. El tipo o diám usual**, para todas las ruedas de carros (0,788 m) 33 pulgs. Peso de cada rueda 281.22 kg (620 lbs) para carro de 30 ton de capacidad, á 326.60 kg (720 lbs) para 50 ton.

**11. Conicidad de la llanta.** Con el objeto de disminuir las resistencias que presentaria una rueda de llanta cilindrica, cuando pasa por las curvas (véase Resistencia de Tren, ¶ 36, p. 000), la transición, desde la llanta a la pestaña de la rueda se hace por medio de una curva, de cerca de una pulg (25 mm) de radio, que usualmente mantiene el lado de la pestaña separado del lado de la cabeza del carril; y la llanta de la rueda se hace en forma cónica (con su diámetro mayor junto a las pestañas), con el objeto de que las ruedas *exteriores* (con tendencia a resbalar siempre hacia fuera del carril) puedan asi girar sobre sus diámetros *mayores*, y las ruedas *interiores* sobre sus diámetros mas *pequeños* : pero debido al tráfico el cono se va reduciendo, y aun llega a invertirse; el diam de la rueda, próximo a la pestaña, algunas veces llega a ser menor que el mas distante de la pestaña, antes de 1907 el cono tipo de la Asociacion de Maestros Constructores era $^{1}/_{38}$. En 1907 el cono tipo se aumentó a $^{1}/_{20}$. El F. C. de Pennsylvania encontró que la rotura de pestañas de rueda disminuyó mucho con el aumento del cono. (Véase Ry Age Gaz, 1912 Jul 19, p. 92.)

**12. Zunchos.** El objeto del zuncho es dar mayor resistencia a las ruedas y resistir el desgaste. Los zunchos van : o forzados sobre las ruedas por reducción de temperatura, o asegurados en una u otra forma de los muchos y diferentes modos que hay de hacerlo, o de ambos modos.

## Frenos.

**13. Un zapato de Freno** es una pieza de metal que por un lado conforma con la llanta y pestaña de la rueda. Ordinariamente, se provee para cada rueda un zapato de freno; pero los frenos de « abrazadera » provistos de dos zapatos de freno, uno a cada lado de la rueda, presentan grandes ventajas. Los dos (o cuatro)

zapatos para un par de ruedas están conectados por *vigas de freno* (con frecuencia armadas para darle mayor resistencia) colocadas paralelamente al eje, entre los dos pares o afuera, segun convenga; o de ambos modos como en el freno de « abrazadera ». Los *contrapesos colgantes de los frenos* están conectados a las vigas de los frenos y carretillas de tal modo que recojan las fuerzas producidas por la friccion de los zapatos contra las ruedas y sostengan los zapatos en su lugar. Un sistema de *Palancas de Freno* distribuye debidamente la presión del freno a todas las ruedas, y conecta las vigas del freno con el origen de la fuerza activante; por ej. : con el eje de la rueda de mano o con el piston del cilindro de aire, o con ambos.

**14. Frenos de aire.** Para la acción de los frenos por aire comprimido, cada carro está provisto de un *cilindro de Freno*, colocado con un émbolo conectado con el sistema de palancas de freno. Cada carro va tambien equipado con un *Tubo de Freno* que corre a todo su largo. El tubo del freno tiene una manguera flexible en cada extremo, y conecciones por donde toda la linea puede unirse, y también con uno o dos *Compresores de aire*, movidos por vapor, que van en la locomotora. Una *válvula de Freno* colocada en la casilla de la locomotora, permite al maquinista manejar los frenos de la locomotora y de todo el tren.

**15. Freno de aire « Directo. »** En este freno, el aire comprimido pasa desde el compresor (o de un recipiente de aire comprimido) en la locomotora, por la válvula de freno del maquinista, y el tubo de freno, directamente a los cilindros de los frenos y los aplica. Su acción, no obstante, no es bastante rápida para trenes largos, y tiene la desventaja mayor de que cualquier falla en la provisión de aire, como una manguera rota, resulta un fracaso de todo el sistema; y esto tanto mas propenso a ocurrir cuanto mas se le exige al sistema.

**16. El freno de aire « automático »** prácticamente elimina estas objeciones. Cada carro tiene un *Recipiente Auxiliar* de aire comprimido, y está provisto con una válvula especial de muchos detalles, conocida como la « *Válvula Triple* ». Obra por diferencias de presión entre el tubo del freno y el recipiente auxiliar del carro. La característica esencial es que una reducción de presión en el tubo del freno (causada por la acción de la valvula de freno del maquinista, por una válvula de emergencia en el carro, o por alguna falla en la linea del tren) obra sobre cada válvula triple de modo que el aire pase por ella desde el recipiente auxiliar de cada carro al cilindro del freno. Para soltar los frenos, el maquinista pone su válvula de freno en posición tal que restablezca la presion normal en la linea del tren; asi que esto sucede la válvula triple permite el escape del aire de cada cilindro de freno, y los muelles apropiados aflojan los zapatos de freno de las ruedas. La valvula del maquinista tiene varias posiciones, por medio de las cuales los frenos pueden (1) aflojarse gradualmente (2), sostenerse todos como se hayan aplicado (3), aplicarse gradualmente, o (4) aplicarse instantaneamente.

**17. « Freno de alta velocidad ».** En éste las presiones empleadas son casi completamente suficientes para calzar las ruedas á pesar del relativamente bajo coeficiente de fricción de los frenos a alta velocidad (vease « Friccion », p. 433). Pero, a medida que la velocidad del tren se reduce, el aire se deja escapar gradualmente, de modo que disminuye el rozamiento de las ruedas a medida que el coeficience de fricción aumenta.

**18. El control eléctrico** de las válvulas, se usa mucho y ha sido empleado para trenes de vapor muy largos donde aun el freno de « aire automático » suele ser lento en su operación. En los carros eléctricos obra un compresor de aire en cada carro accionado por un motor eléctrico en ese carro.

**19. Los frenos electricos** se han usado mucho en tranvías electricos. En el freno eléctrico Westinghouse se hace que los motores del tranvía generen electricidad que magnetiza un zapato que va directamente sobre cada carril. El zapato entonces se pega al carril, y el arrastre que resulta fuerza los zapatos de los frenos contra las ruedas. Los frenos eléctricos, que dependen de la rotación de los motores, no pueden sostener un carro que esté parado en una pendiente.

**20. Nuevo freno de alta velocidad.** La Cia de Frenos de Aire Westinghouse junto con el F. C. de Pennsylvania (S. W. Dudley, auxiliar del Ing Jefe Soc Am de Ings Mec, N. Y. Seccion, 1914 Feb 10) probaron en todas formas un freno nuevo de aire, con los siguientes resultados:

Tren de 12 carros de pasajeros, de acero y loco moderna; largo total cerca de 300 m; peso total cerca de 1000 tons.

| | | | | |
|---|---|---|---|---|
| Velocidad en kilómetros por hora... | 48 | 96 | 128 | |
| Freno ordinario paro el tren en..... | | 480 a 540 | | metros. |
| — nuevo — — ..... | 60 | 300 | 600 | — |

**21. Frenos de vacio.** No se han empleado mucho. Su modo de obrar es casi el mismo que el del « freno de aire » (comprimido). Como es por consiguiente imposible obtener presiones de mas de 1 kg por cm cuad, se necesitan cilindros de freno muy grandes; pero el aparato tiene la ventaja de que, en caso de accidente del servicio de aire, los frenos se aplican automáticamente, sin el uso de la « valvula triple ».

## Miscelánea.

**22. Las señal de aire y el aprovisionamiento de vapor** en los trenes de pasajeros se hacen por medio de lineas de tubos separadas y tendidas a lo largo del tren, cada una conectada entre los carros y locomotoras, por conexiones de manguera. El principio fundamental de la señal de aire es parecida a la del freno de aire automático, en el que la presion del aire se mantiene normal en la tuberia, y el trabajo (en este caso el soplido del pito, en la casilla), se hace por el escape de aire, (1) efectuado por una válvula sobre la que obra una cuerda de señal en el carro; o (2) de un salidero, como el que puede ocurrir por la rotura del tren en dos.

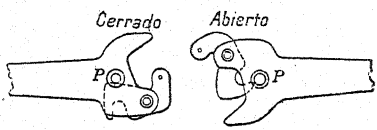

Fig. 3

**23. Enganches.** Se dispone uno en cada extremo del carro, simetricamente con respecto al eje vertical por el centro del carro (la quijada abierta con la cara a la izquierda cuando uno está parado en el terreno de frente al carro), asi que carros y locos pueden siempre engancharse juntos sin invertir el carro ni el enganche. La fig. 3 muestra dos enganches casi enganchados; uno abierto y uno cerrado. Las *muelas* van trancadas por medio de los pasadores, *P*, *P*, de tal modo, que con cualquiera *muela* abierta, los carros se conectarán cuando se junten, sin posterior atención para el personal del tren, tambien, cualquier enganche puede abrirse, y los carros desengancharse, por medio de una palanca en una esquina del carro, sin necesidad, para el personal del tren de estar entre los carros. No obstante las mangueras del tubo del tren deben conectarse y desconectarse por un hombre que si tiene que estar entre los carros; pero se han introducido mejoras por las cuales esto puede hacerse automaticamente sobretodo usando tracción eléctrica de unidad multiple. Los enganches son movibles en dos planos para poder girar en las curvas.

**24. Estos enganches** forman una combinación, en cada extremo del carro, de una barra longitudinal corrediza, con muelles para soportar el choque cuando arranca. Los muelles hacen posible también aproximar, el arranque del tren a la distancia de un carro a un tiempo lo que es importante, porque las resistencias de arranque son mayores que las del recorrido normal. En el *Enganche de Friccion*, se usan accesorios de fricción que sirven para absorber el rechazo de los muelles, evitando así la acumulación de los choques rítmicos repetidos.

## Sección libre.

**25. En los puentes,** véase pag 807. En túneles, la Asen Am de Ings de F. C. ha recomendado las secciones indicadas en la fig. 4, entre el centro de la via y el costado del túnel.

**26. En las curvas** se necesita una sec libre adicional y puede ser calculada por las siguientes fórmulas dadas por Jorge Paaswell, Ingeniero auxiliar, de la Comisión del Servicio Público de la ciudad de Nueva York, en la revista Ingeniería y Contratos, 1914, marzo 25, p. 367. En la fig. 5, sea :

$a$ = dist entre centros de carretillas;
$L$ = largo del carro;
$c$ = dist desde el medio de la linea de centro del carro al centro de la curva de la via;
$e$ = dist desde la linea de centro en el extremo del carro, al centro de la curva de la via;
$R$ = radio de la curva.

Son preferibles todas las unidades en pies.
Entonces, $c = a^2/8\ R$ ; y $e = (L^2 - a^2)/8R$.
Vease también esta materia en curvas, pag. 807.

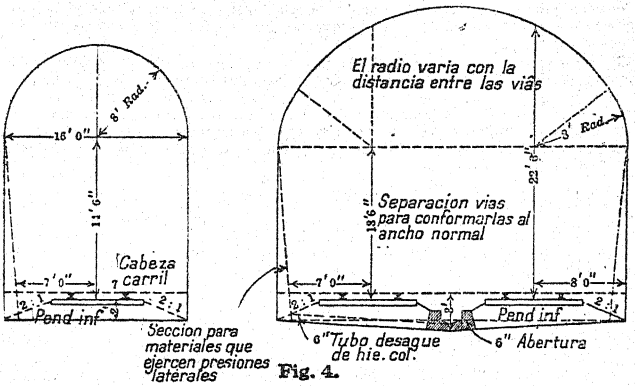

Fig. 4.

**27.** Where

**27.** Donde se usen **curvas de transición o « espirales »**, el radio puede tomarse, como el de la curva en el medio del carro. Para el radio de la curva de transición, $R_t$, en cualquier punto, tenemos $R_t = R_c\ T/t$ ; donde $R_c$ = radio de la curva circular; $T$ = largo de la curva de transición; $t$ = dist del punto desde el comienzo (T. E.) de la curva de transicion.

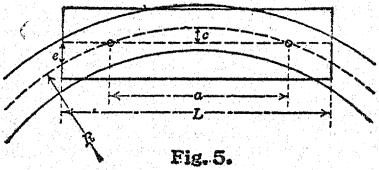

Fig. 5.

**28. Tumba del carro.** En adición a esto, debe darse margen, en el lado interior de la curva, cuando menos, para el ladeo del carro debido al peralte del carril. Esto, por supuesto, puede calcularse facilmente, dando el peralte, ancho de via, y altura del alero del techo u otro dato de influencia.

**29. Unas fórmulas mas precisas** y diagramas detallados para estos cálculos los da Mr. Frank H. Carter en Ingenieria y Contratos, 1913, dec 10, pp. 650-2.

## LOCOMOTORAS

**30.** En la siguiente descripción de una loco hemos seguido aproximadamente, el orden en que la energia se trasmite. Véase la fig. 6, tipo de una loco moderna donde se muestran las relaciones generales y proporcion de sus diversas partes.

**31. El tender** (no mostrado) es un carro corto de dos carretillas, con estanques para agua, y espacio para carbon (o estanques para aceite combustible). Se usan placas divisorias dentro del estanque para evitar movimientos violentos del agua. Algunas veces, especialmente en el servicio de carga y cortes, el agua y el combustible se llevan directamente sobre la locomotora, donde sirven para aumentar con su peso la « adhesión ». Los tender llevan algunas veces un cucharón embisagrado que puede bajarse casi a nivel de las traviesas, dentro de una canal tanque, véase, pag. 1090, y entonces, por virtud de la velocidad del tender, hace que el agua se levante desde el estanque canal por el tubo que lleva el agua al tender del estanque. En todos los casos, el agua se lleva a la loco por una manguera de conexión.

**32. Hogar.** El carbón pasa por la puerta de fuego (a veces movida por la misma máquina) al hogar donde cae sobre las parrillas (promedio de superficie 37 pies cuad *) (como 3,50 m cuad) que están hechas de barras de hierro fundido. Un cenicero está suspendido bajo las parrillas, para evitar que las cenizas caigan sobre la via. **Los alimentadores mecanicos de carbon** se están usando en las locos pesadas. Su principal ventaja es que ponen el carbon en el fuego mucho mas rápidamente que el fogonero.

**33.** Los gases calientes del fuego pasan por **los tubos** (no mostrados) y que practicamente llenan la caldera y van a lo largo de ella. (Promedio de superficie de calefaccion 2,422 pies cuad *. En el extremo del frente, los gases calientes se descargan de los fluses en la « **caja de humo** », y de ahi hacia arriba por la **chimenea.**

**34. La caldera** se extiende desde la caja de humo en el frente, a la caja de fuego o fogon atrás, y abarca los costados y parte de arriba del hogar. El fogon u hogar y los tubos estan rodeados enteramente de agua, dando asi una gran superficie de calefacción. El agua se introduce en la caldera por un **Inyector** (no mostrado). La altura del agua en las calderas, puede observarse por el **Nivel**, probarla y registrarla por medio de las **Llaves de prueba** (no mostradas). También hay un **manómetro** y una **válvula de Seguridad, Tarugos Fusibles,** etc. (no mostrados) todo se usa lo mismo que en las calderas fijas.

**35. La cúpula de vapor** está en la parte superior de la caldera, y en ella se aloja el vapor mas caliente y seco. De la cúpula, el vapor se puede hacer pasar por la Válvula de Cuello (manejada por una palanca en la casilla y por el « *Tubo Seco* ») grande (indicado en la fig. con lineas de puntos) hacia las cajas de vapor en los cilindros.

**36. Supercalentadores** se usan ahora en todas las locomotoras nuevas. Despues de dejar el vapor la cúpula, pasa en la caja de humo por muchos tubos pequeños, que presentan una gran superficie externa de calefaccion, y reciben los gases calientes que se escapan en los extremos del frente de los tubos. El vapor asi es recalentado a una temperatura mucho mas alta que la que corresponde a su presión cuando está en presencia del agua. La economia estriba principalmente en que no se hace la condensación en los cilindros, a pesar de la caida de una parte de la presión debido al paso por tantos tubos pequeños. La economia llega, en máquinas simples, hasta a un 25 %, con temperaturas de cerca de (600° F) 315° C.

**37. Un recalentador** es practicamente un supercalentador colocado entre los cilindros de alta y baja presión de una maquina compuesta.

---

* Promedio ó total para las locos en los E. U., junio 30, 1914 (excepto las loco en servicio de los llamados pequeños ferrocarriles y de compañias terminales, Mallet y locos sin clasificar), segun la Comision Interior de Comercio « Estadisticas de F. C. en los E. U., 1914.

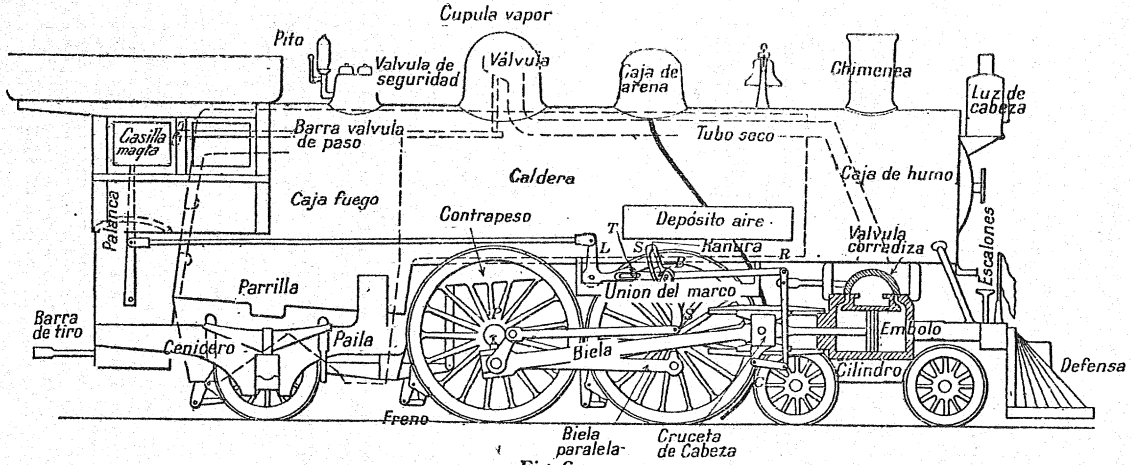

**Fig. 6.**

El aparejo de válvula de distribución Walschaerts está indicado arriba en esquema. Dos movimientos « simples, armónicos » se resuelven en uno, y se trasmite a la válvula de distribucion, por la barra vertical que tiene su parte superior en *R*. (1) El movimiento horizontal en *C* viene directamente desde la cruceta. (2) El movimiento horizontal en *R* está determinado (*a*) por el movimiento del cuadrante oscilante ranurado, *S S*, y (*b*) por la *posicion* de la palanca, *L*. El bloque del cuadrante, *B*, está pivotado en la barra *T R*, y puede deslizarse hacia arriba o hacia abajo en la ranura *S S*, y puede ser sostenida a cualquier nivel por la palanca de cambio. Entonces la barra *T R* recibe del cuadrante *S S*, un movimiento, hacia alante o hacia atrás, grande o pequeño, con cualquier movimiento dado y que depende de la posición del bloque *B*. Como está dibujado arriba, la posicion de *B* es opuesta al pasador de *S S*, y no tendria por consiguiente movimiento horizontal. En la práctica, la ranura y pasador *T*, están a veces sustituidos por un cuandrante vertial, no indicado conectando el extremo hacia adelante de la biela (mucho más alto de lo que se ve), con el extremo de atrás de la barra horizontal *TR*.

**38. Cilindros.** De el « tubo seco » o desde el supercalentador el vapor pasa por las *cajas de vapor* y las *Válvulas de Corredera* a los cilindros, donde empuja los émbolos y sus barras. Hay una válvula pequeña llamada *de purga* del cilindro (no mostrada), en cada extremo de cada cilindro, que se maneja desde la casilla permitiendo al maquinista botar el agua que se deposite en ellos. También hay válvulas atmosféricas en los cilindros, que permiten el libre movimiento de los émbolos atrás y adelante cuando la válvula del cuello está cerrada.

**39. Válvula de distribución.** Las valvulas que admiten vapor en los dos extremos de cada cilindro alternativamente son planas o cilíndricas. Varios sistemas se emplean tanto para equilibrar las presiones del vapor contra las válvulas como para reducir la fricción. Las válvulas han sido hasta ahora generalmente movidas por el movimiento « *Stephenson* » de excéntrica y cuadrante muy corriente en máquinas fijas. En el aparejo Walschaerts, que está generalizándose, las principales ventajas son debidas a su situacion enteramente fuera de las motrices o voladoras que lo hace accesible para aceitarlo, etc., y que permite trabarlo y cruzarlo mas con mas firmeza del marco o bastidor de la loco, véase p. 1.117.

**40. El cambio y corte** esta manejado por la palanca de cambio en la casilla. En locos pesadas se están generalizando los aparejos de rosca operados a mano, y también por fuerza artificial. Son de varios tipos diferentes.

**41. Las barras de los émbolos** son guiadas por las « **crucetas** », y van conectadas a la bielas de las motrices (voladoras) por « **barras de conexion** » (bielas). Las bielas, en el lado derecho e izquierdo de la loco, están colocadas a ángulo recto entre si, sobre el eje; de modo que cuando una biela esté en « punto muerto », e incapacitada de hacer fuerza y girar la otra produce su efecto máximo. Los varios pares de motrices van conectados entre sí por « **barras paralelas** », a cada lado de la loco.

**42. Contrapesos.** Los contrapesos van colocados en las motrices opuestas al pasador o muñon de la biela, para equilibrar el peso de las partes que giran. En locos de dos cilindros, se agrega un exceso al contrapeso, para neutralizar el efecto de las partes recíprocas, que de otro modo producen en la loco esfuerzos peligrosos, cuando corre a alta velocidad, en un plano horizontal. Algunas veces se usan cuatro cilindros, y cada émbolo va a una biela separada, y las dos bielas en el mismo lado de la loco van colocadas a 180° de separación, de modo que sus partes recíprocas se equilibren mas con las otras; así no se necesita exceso de peso.

**43. Pestañas.** Anteriormente, en locos de tres o mas pares de motrices solo las llantas del frente y los de atrás en cada lado tenian pestañas; las voladoras (motrices) intermedias se dejaban sin pestaña o « planas », para facilitar el paso por las curvas : pero se está generalizando ponerle pestañas a todas las llantas de las motrices, y se facilita el paso por las curvas dándole a las motrices de atras y delante mayor « juego », entre la pestaña y la cabeza del carril.

**44. El marco o bastidor** (no mostrado) lleva la caldera, fogon, casilla, cilindros y la mayor parte de los accesorios. El peso se trasmite del bastidor por medio de los muelles y por un sistema de palancas, que distribuyen la carga, como se desee, sobre los ejes y cajas de las voladoras y sobre las ruedas de la carretilla.

**45. Auxiliares.** Ademas de los aparatos usados en las máquinas fijas, la loco tiene un *Pito* de vapor; una *Campana* (algunas veces movida por aire comprimido), y una *Farola* de aceite acetileno o eléctrica. La farola eléctrica, a pesar de su fuerza para alumbrar la vía, es de dudosa ventaja debido a la brillantez de sus reflejos blancos sobre las cristales de señales de color, y al efecto de encandilar al personal del tren que llega en direccion opuesta. Algunas veces las farolas van en pivotes y giran automáticamente cuando pasan por las curvas; o a voluntad del maquinista. También hay *Escalones* y *Pasamanos* para subir a la locomotora y para llegar a varias partes de ella; *Grampas* para bandera y farol : luces de casilla y otros accesorios; una « *Defensa* » (para apartar obstrucciones accidentales); y una *Caja de Arena* con válvula y tubo, para llevar la arena sobre el carril directamente en frente de las ruedas motrices para aumentar la adhesion.

**46.** En locos de **expansion** (1.333 4 cyl de expansion, y 659 2 cilindros de expansion, entre el total de 63,510 locos *), la expansion se efectua generalmente al través de dos o, cuatro cilindros. Las areas de alta y baja presión de los émbolos son de 1 a 2.5 aprox. Donde se empleen dos cilindros, el cilindro de alta presión va colocado a un lado de la loco, y el de baja presión en el otro; y los dos estan conectados por un gran « *Tubo Colector* », provisto de una « Valvula de Incomunicar » por la cual el vapor a alta presión puede admitirse a voluntad directamente de la caldera al cilindro de baja presión, para hacer arrancar la loco cuando el cilindro de alta esté en « punto muerto » o para hacer temporal y anormalmente un gran esfuerzo. Donde se usen cuatro cilindros van colocados un cilindro de alta y otro de baja presión a cada lado de la loco, dispuestos uno detrás del otro accionados por la misma barra de émbolo o apareados uno al lado del otro, el cilindro de alta va dentro, o bien uno encima del otro. Cuando van apareados uno al lado del otro, cada émbolo actúa sobre una biela separada, cada biela va colocada a diferente cuadrante. Esto logra casi un equilibrio perfecto entre las partes recíprocas. La economia en combustible y agua lograda por la expansión dispuesta de este modo varia de 10 a 25 por ciento, segun el servicio que se haga. La economia se pierde a menudo, por lo menos en parte por el aumento del costo de reparaciones, debido a la mayor complejidad de esta disposición.

## Datos sobre las Locomotoras.

**47. Las siguientes tablas** dan datos extremos aproximados de la construcción de loco alrededor de 1913 segun los catalogos de los manufactureros.

**48. Práctica general.** Como lo indican las listas de tipos de locos en uso por el F. C. de Pennsylvania, varian desde un mínimo alrededor de la mitad entre nuestro tipo maximo y mínimo hasta un maximo igual o que ligeramente excede a nuestros máximos en las tablas. La loco corriente en uso, por consiguiente, cae bajo nuestro máximo, alrededor de $^1/_4$ (o $^1/_5$ si incluimos los F. C. pequeños) de la diferencia entre nuestros maximos y mínimos. Promedio de peso de las loco, excluyendo el tender, cerca de 166.000 * lbs (como 75.300 kg.).

**49.** La columna encabezada « **Clase** » da (1) el número de ruedas bajo la loco, segun el sistema Whyte, el primer número indica el número de ruedas de la carretilla al frente, el segundo número es el de las motrices, y el tercero el número de ruedas que siguen; y (2) la nomenclatura de los Talleres de Locomotoras « Baldwin ».

**50.** Bajo « **Servicio y Tipo** » se da (1) la clase de servicio y (2) el nombre popular comercial del tipo.

**51. Base de rueda** es la distancia a lo largo del carril, entre los puntos de contacto con los carriles de las ruedas del frente y de atrás.

**52. La Fuerza de tracción**, dada en cada caso, es la fuerza horizontal que la loco puede ejercer, siempre que las ruedas no resbalen. La que se calcula por la fórmula siguiente para locos simples, es aproximada. Es buena para velocidades hasta cerca de diez millas (16 kilometros) por hora.

$$\text{Fuerza de tracción} = \frac{d^2\, S\, (0{,}85\ P)}{D} \ (\dagger) = \text{usualmente entre } 0{,}22 \text{ y } 0{,}25 \text{ del}$$

peso en todas las motrices.

$d$ = diámetro, de un cilindro, en pulgs;
$S$ = carrera del émbolo, en pulgs (en un sentido);
$P$ = presión de la caldera (a la cual estan adheridas las válvulas de seguridad), lbs en por pulg cuad;
$D$ = diámetro de las motrices en pulgs.

Para locos de expansión de dos cilindros, úsese 0,60 en lugar de 0,85, y hágase:
$d$ = diámetro del cilindro de alta presion.

---

* Promedio o total para todas las locos en los E. U., 1914, junio 30 (excepto locos en el servicio de los llamados pequeños ferrocarriles y los de compañias terminales, Mallet y locos sin clasificar, según la comision de comercio entre estados. « Estadísticas de F. C. en los E. U. » 1914.

(†) (*N. del T.* — Poniendo el diám del cilindro, la carrera del émboly el diam de las motrices en centímetros y la presión d. la caldera en kilogramos por centímetros cuad la fuerza de tracción viene en kilogramos.)

Para las loco de cuatro cilindros de expansion, la formula se convierte en :

Fuerza de tracción $= \frac{d_l^2\, S\, (1.6\, P)}{(d_l^3/d_h^2 + 1)\, D}$ en la cual $d_l$ y $d_h$ son los diametros en pulgs de los cilindros de alta y baja presión respectivamente.

**53. Fuerzas de tracción a altas velocidades.** Los siguientes datos los suministra la American Locomotive Co en la tabla 9 de su Boletin n.º 1.002. Multipliquese el esfuerzo de traccion, calculado por la fórmula, por el correspondiente factor dado en la siguiente tabla :

| Velocidad del embolo en pies por min | 300 | 350 | 400 | 450 | 500 | 550 | 600 | 650 | 700 | 750 | 800 |

**55.** Vease Tabla de **Dimensiones** de Locomotoras en la prox página.

* Aproximado.

**56. Locomotoras Mallet articuladas.** Se usan algunas veces para servicio de carga pesada. La loco Mallet tiene sus motrices divididas en dos grupos, cada grupo está contenido en un bastidor separado y movido por un par de cilindros separados; cada par de cilindros tiene su aparejo de movimiento de válvula distinto, etc. Los bastidores de atrás están asegurados en rígida alineacion con la caldera. Los bastidores del frente están embisagrados o articulados al frente del bastidor de la máquina de atrás. El frente de la caldera (generalmente se dedica a supercalentadores y accesorios similares, por lo excesivamente largos que resultarian los tubos) va soportado por el bastidor del frente de la máquina, que es siempre mas o menos facil prolongarlo por debajo. Algunas veces la caldera está construida de modo que se doble en una union llamada de « acordeon ». La Mallet tiene la necesaria flexibilidad para pasar curvas y permite el uso de un doble numero de motrices en una loco de bastidor rígido. Las dos máquinas van invariablemente dispuestas para trabajar por expansión, los cilindros de atrás obran a alta presión y descargan su vapor de escape, por conexiones flexibles a la máquina de adelante, que trabaja a baja presión. Los resultados dan un gran aumento de fuerza de tracción por locomotora y personal dado, y, economia de combustible para un tonelaje dado de tren.

## Locomotoras en el trabajo.

**53. Combustible y agua usada.** Una loco poderosa típica, que lleve un tren corriente de pasajeros evapora de 25,900 a 30,000 libras (11,300 a 13,600 kg) de agua por hora, quemando de 3,500 a 5,000 libras (1,590 a 2,270 kg) de carbon; o sea de 75 a 100 lbs/milla (21 a 28 kg por kilometro). (Catecismo de Locomotora, Forney, por George L. Fowler.)

**59.** Las locos de pasajeros generalmente llevan combustible y agua suficiente para 60 u 80 kilometros; algunas de 100 a 110. En los trenes de carga, es suficiente para 30 ó 38 kilometros. Vias o divisiones, con fuertes pendientes exigen estaciones de combustible y agua mas cerca unas de otras que cuando las pendientes son mas suaves.

**60. Capacidad de arrastre.** Las siguientes tablas dan las cargas en toneladas (sin contar la loco y tender) que las locos arriba descritas pueden arrastrar, a velocidades usuales, sobre una via recta y en diferentes pendientes. Las cargas están basadas, considerando que la llamada « adhesion » de la loco no es mas del 25 % del peso sobre todas las motrices, y que las condiciones de la via y carros es tal que la resistencia a la friccion de los carros no excede alrededor de 7 u 8 lbs por tonelada de 2.000 lbs (o sea de 0,35 a 0,40 %) de su peso. Estos son ordinariamente condiciones favorables. La adhesion es rara vez menor de un quinto ni mayor de un tercio, del peso sobre las directrices.

### 61. Ancho de via Tipo; 4 pies 8 ½ pulgs (1,435 m).

Tabla de cargas, en toneladas de 2.000 lbs (907 kg) que arrastrarán las locomotoras en diferentes pendientes.

| Clase. | Servicio y Tipo. | | En una pendiente de: 0 por ciento = 0 pies/milla | ½ por ciento = 26.4 pies/milla. | 1 por ciento = 52.8 pies/milla. | 2 por ciento = 105.6 pies/milla. | 3 por ciento = 158.4 pies/milla. |
|---|---|---|---|---|---|---|---|
| 4-4-0 | Pasajeros | Min.. | 575 | 265 | 160 | 80 | 45 |
| 8-*C* | American | Max.. | 2657 | 1181 | 678 | 348 | 213 |
| 4-6-0 | Pasajeros y Carga | Min.. | 1014 | 380 | 227 | 114 | 70 |

### 62. Via Estrecha; 3 pies 0 pulg (0,914 m).

Tabla de cargas, en toneladas de 2.000 lbs (907 kg) que arrastrarán las locos en diferentes pendientes.

| Clase. | Servicio y Tipo. | | En una pendiente de : 0 por ciento = 0 pies/milla. | ½ por ciento = 26.4 pies/milla. | 1 por ciento = 52.8 pies/milla. | 2 por ciento = 105.6 pies/milla. | 3 por ciento = 158.4 pies/milla. |
|---|---|---|---|---|---|---|---|
| 4-4-0 | Pasajeros | Min.. | 445 | 205 | 120 | 60 | 30 |
| 8-*C* | American | Max.. | 1380 | 550 | 330 | 165 | 100 |
| 4-6-0 | Pasajeros y Carga | Min.. | 1000 | 380 | 227 | 114 | 70 |
| 10-*D* | 10-Ruedas | Max.. | 3718 | 1407 | 840 | 438 | 278 |
| 2-8-0 | Carga | Min.. | 860 | 400 | 245 | 127 | 79 |
| 10-*E* | Consolidado | Max.. | 3100 | 1460 | 900 | 480 | 310 |
| 0-6-0 | Patio | Min.. | 310 | 145 | 85 | 45 | 25 |
| 6-*D* | | Max.. | 3718 | 1407 | 840 | 438 | 278 |

**63. La eleccion** de una loco dependerá del servicio y sus requisitos, y estará limitada por las secciones de paso de los puentes, túneles, etc., resistencia de puentes, y peso del carril; este último se considera suponiendo que cada 10 lbs por yarda (4,96 kg por metro) de carril soportara una carga de 3.000 lbs (1.361 kg) sobre cada rueda; con esto para carriles que pesen de 90 a 100 lbs/yarda (44.64 a 49,61 kg/metro) permite cargas de 50.000 (22.680 kg) a 60.000 lbs (27.215 kg) por *par* de ruedas motrices.

**64. Máquinas de Patio** (9,881 en uso *). Son de tipos 0-4-0, 0-6-0 o 0-8-0; usualmente 0-6-0. Porque estas locos rara vez corren a altas velocidades, el cabeceo no es fácil que ocurra (véase ¶ 67) las ruedas de carretilla no son necesarias, y sin ellas, al concentrar el peso de la loco sobre las motrices, resulta el esfuerzo de tracción máxima.

**65. Locos de Carga** (37,405 en uso *) son de los siguientes tipos 4-4-0 « *American* » para servicio ligero; 2-6-0 « *Mogul* » y 4-6-0 « *Diez-ruedas* » para servicio mixto : 2-8-0 « *Consolidado* » y 2-8-2 « *Mikado* » para pendientes fuertes y trenes pesados; tambien se estan generalizando los tipos 2-10-2 « *Santa-Fe* » : y « *Mallet Articulado* » para servicio pesado y pendientes fuertes.

**66. Locos de pasajeros** (14,090 en uso *) sus tipos son 4-4-0, 4-4-2 « *Atlantic* » 4-6-0, 4-6-2 « *Pacific* »; y recientemente, 4-8-2 « *Montaña* ».

**67. Las ruedas de carretilla** evitan el cabeceo a altas velocidades y ayudan a guiar la loco al pasar las curvas. El tipo 2-8-2 « Mikado » está especialmente adaptado para correr en cualquiera dirección.

**68. El diam de las directrices (voladoras)**, en pulgs no debe en general ser menor que la velocidad max en milla/hora.

**69.** La fuerza y velocidad de las locos, y su consumo de combustible y agua, varia mucho con las circunstancias, tales como : pendientes, curvas, condicion de la via

---

* Promedio ó total para todos las locos en los E.U., 1914, junio 30 (excepto locos en el servicio de los llamados pequeños ferrocarriles y tambien en los de las compañías terminales, Mallet y locos sin clasificar, según la comisión de comercio Interior « Estadísticas de F. C. en los E. U. », 1914.

y material rodante; numero de carros en el tren; diámetros, número y dist (aparte), de las ruedas de carro; sistema de enganches; habilidad del corredor de la loco y de su fogonero, etc., etc.

**70. Recorrido.** Las siguientes cifras están tomadas y deducidas del Informe de la Comision de comercio entre Estados de los E. U. en 1914:

| | Millaje de Locomotoras. Pasajeros. | Carga. | Todas clases. |
|---|---|---|---|

**Recorridos Rápidos.**

**71.** Como parece evidente de que los manufactureros han llegado al limite de la resistencia de sus carriles, el aumento de peso del material rodante ha tendido a restringir las velocidades. El F. C. de Pennsylvania limita la velocidad de sus trenes de pasajeros en general a 70 millas (como 112 kilómetros) por hora, con limites menores en ciertas localidades, y el F. C. de Baltimore & Ohio, tiene limites de 60 millas (como 96 km) por hora.

**72.** Entre los **itinerarios notables mantenidos con regularidad** están los que siguen:

| Ferrocarril. | Tren y Ruta. | | Dist en kilometros. | Promedio velocidad km/hora. |
|---|---|---|---|---|
| Phila & Reading. | Cada Hora. | Phila. | Jersey City. | 145.1 | 88.8 |
| | | Camden. | Atlantic City. | 88.8 | 97.5 |
| Pennsylvania.... | | N. Phila. | Harrisburg. | 167.2 | 81.9 |
| | ...Broad'y Ltd. | New York. | Chicago. | 1,462.4 | 73.1 |
| N. Y. Central... | 20th C Ltd. | New York. | Chicago. | 1,570.7 | 78.5 |

**73. Para apreciar la velocidad** de un tren ú otro vehiculo, en el que se viaja, se cuentan espacios conocidos, tales como, largos de carril, dist entre postes telegráficos, o revoluciones de una rueda en un tiempo dado. Los largos de carril pueden, a veces, contarse por el sonido de las ruedas al pasar por las bridas (juntas); y las revoluciones por cualquier irregularidad de la rueda.

**74.** Sea $L$ = el largo de uno de los espacios iguales conocidos;

Entonces:

Velocidad V por segundo = numero de tales largos pasados en $n$ segundos, (digamos $N$ largos) multip. por $L$ y dividido por $n$ es decir $V = \frac{N \times L}{n}$.

## CARROS

**75.** En uso * 53,466 carros de pasajeros, 2,325,647 de carga, 124,709 de miscelánea. Véase también « carretillas », etc., ¶ 2. Practicamente todos los carros Americanos, excepto algunos carros de cola para personal, y de descarga de minerales, están construidos con dos carretillas cada uno, fig. 7; cada carretilla tiene 2 o 3 pares de ruedas. En carretillas de 6 ruedas, los muelles y balancines distribuyen la carga por igual, o aproximadamente, entre los tres ejes. Sobre los platos de centro de ambas carretillas descansa un marco o « cama » rigida, larga para formar el cuerpo del carro. Esto fué anteriormente diseñado para soportar todos los esfuerzos de tracción de la carga longitudinal y verticalmente; pero los costados de los carros están hechos ahora, hasta donde es posible, como vigas armadas, aligerando asi y reforzando a la vez el carro. Las camas o marcos anteriormente se hacian de madera, generalmente atirantadas con sopandas de hierro; pero ahora se hacen casi universalmente todas de acero.

**76. Acero.** Los cuerpos de carro son de madera ó acero, o mas generalmente, y sobretodo en los carros modernos de carga, combinaciones de armazón de acero con pisos y cubiertas de madera. Los carros de carga, todos de acero se han usado mucho tiempo antes que los coches de pasajeros todos de acero. El uso del acero

* Véase nota al pie, página 1123.

en todo, excepto para cierto amueblado interior, se ha establecido prácticamente como tipo para todo el equipo de carros de pasajeros en lineas principales importantes, comenzando alrededor de 1905 a 1910. En peso, los carros de acero tienen prácticamente el mismo promedio *por pasajero* que los carros de madera, aunque tienen generalmente de 10 a 20 por ciento mas de peso total y de capacidad para pasajeros. Son mucho mas fuertes, y estan considerados como mucho mas seguros que los carros de madera en caso de accidente y en caso de fuego. Debido a la alta conductividad del calor por al acero son casi siempre desagradables cuando hace mucho calor o frio, a pesar de los trabajos de aislamiento hechos con células de dobles tabiques.

**77. Datos.** La siguiente tabla da aproximadamente las dimensiones maximas y minimas y también peso, etc., de carros de acero.

Dimensiones aproximadas, etc., de Carros de acero.
Pasajeros y Carga, hasta 1908.

(*N. del T.* — Entre paréntesis y *debajo* de cada cita estan los piés convertidos en metros, y las libras en kilogramos.)

**78. Carros de Carga.** Como puede verse en una tabla, publicada en la Revista de F. C. é Ingenieria, feb 10, 1912, donde se recopilan datos de 11 grandes ferrocarriles que poseem sobre 450,000 carros de carga y por un periodo de tres años, el promedio de duración, costo, etc., de los carros de carga es el siguiente :

Promedio de duración de todos los carros, alrededor de 10 años. Cada carro es reparado por término medio una vez al mes, con un costo de $6.26 cada vez. El promedio de recorrido de cada carro por año, 10,400 millas (como 16.700 kilómetros) de lo que resulta en reparaciones $0.007/milla ó sean $0.0043 por kilómetro.

**79. Carros de pasajeros.** El promedio de duración es alrededor de 16 años. Promedio anual de reparaciones, incluyendo pintura, $300 a $700; para carros de correo y expreso $150 a $300. El promedio del peso de un carro de pasajeros es unas diez veces el de su carga completa de pasajeros.

**80. Carros de descarga.** Los hay de varios diseños. Pueden descargar por el fondo, por uno o mas « tolvas » (usualmente transversal, pero algunas veces longitudinalmente), o por los costados, en cuyo caso los costados se levantan o abren hacia afuera, o tambien los costados permanecen practicamente estacionarios mientras todo el piso del carro se inclina, formando asi una abertura bajo el costado y una rampa para que el material resbale. Los distintos fabricantes de carros por medio de varias combinaciones de costados embisagrados y piezas de fondo hacen posible la descarga del material entre los carriles, o, a un lado ó a ambos lados de la via. Los carros de descarga por el fondo se operan ordinariamente a mano, las puertas o postigos se sneltan rápidamente para abrirlas, y se cierran enrollando las cadenas por medio de maniguetas. Los carros con fondo de tumba son frecuentemente operados por aire comprimido, y, en algunos casos, el manejo es algo laborioso; a veces es posible también tumbar toda la carga simultaneamente lo mismo a la derecha que a la izquierda, o a ambos lados, derecha e izquierda en carros alternados, pero siempre bajo el cuidado de un operador, en cualquier punto, del tren.

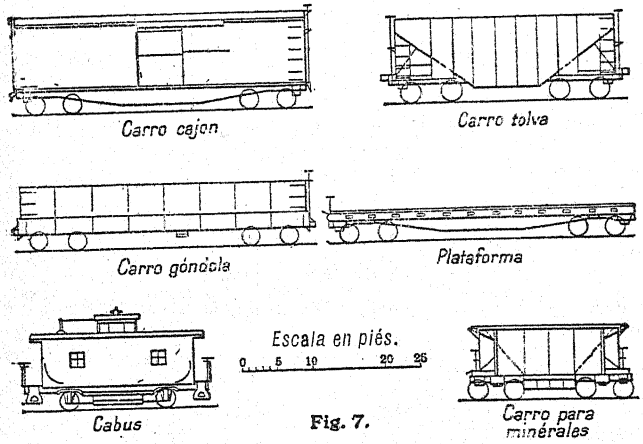

**Fig. 7.**

**81. Carros para minerales** (véase fig. 7). Son hechos anormalmente cortos. y, relativamente de pequeña capacidad volumétrica, porque los carros mas largos resultan ineficaces llevando minerales, que son mucho mas pesados que el carbón y los otros materiales que se llevan mas comunmente.

**82. Carros gruas.** Son usados sobre todo para despejar descarrilamientos y choques, para excavaciónes y manejo de tierra, para mover la via, y para dar carbón a las locomotoras.

**83. Gruas locomóviles.** Parecen ser sumamente útiles para estos trabajos. Tienen movimiento propio y rápido de un lugar a otro.

**84. Las paleadoras de vapor, y martinetes** montados en carros en varios estilos son fabricados por muchos manufactureros.

**85. Los extendedores de balasto** están mencionados en la pag. 894.

**86. Los arados de nieve** echan la nieve fuera de la via (a ambos lados para via sencilla, y a la derecha para via doble); o son del tipo » *rotativo* », en el que una rueda grande cortante gira en el extremo del frente, en un eje longitudinal horizontal, por medio de máquinas poderosas, a menudo movidas por una caldera de locomotora de tamaño completo, y que remueve la nieve, sobretodo, por la fuerza centrífuga desarrollada en la rueda cortante. En lineas ferreas por vapor, el arado se empuja en la nieve por una o mas locomotoras, empujando detras del arado; mientras que, en tranvias eléctricos, el arado o *barredor* (que realmente barre sin emplear la fuerza centrífuga), se mueve hacia adelante por su propia fuerza, las escobas o cepillos se hacen girar con motores independientes. Algunos arados están dispuestos de tal modo que las superficies desviadoras pueden forzarse hacia afuera por el aire comprimido (cuando hay espacio suficiente), lanzando así la nieve mas lejos de la via, y por consiguiente con menor posibilidad de volver a la via.

**87. Limpiadores.** Son piezas, generalmente de planchas de hierro o acero, formadas de tal modo que pueden bajarse sobre los carriles directamente en frente de las ruedas, para quitar unas pocas pulgadas de nieve o hielo que puede haber sobre el carril o a lo largo de su cara interior. Algunas veces se ponen en las locomotoras, y generalmente se agregan a los arados.

**88. Carros de « despejo ».** * Estan diseñados para determinar la proximidad de los objetos en toda la via. Los carros de *despejo* construidos por el F. C. de Pennsylvania y Baltimore & Ohio tienen montados sobre una de las carretillas un marco transversal al carro, cuyo ancho es algo menor que el probable ancho mínimo libre de la via. A este marco están fijados por medio de pivotes, a intervalos de cerca de medio pie, brazos movibles, que se proyectan cerca de dos pies fuera del marco. Cada brazo está provisto de una escala, graduada de tal modo que indica directamente el numero de pulgadas que se han desviado hacia adentro de su posicion extrema. El carro corre por la via, cerca de 4 millas por hora, donde hay que pasar varios objetos, como puentes, estaciones, túneles, etc.; los brazos son desviados hasta que den paso y, los que se desvian queda marcado y anotado. Por supuesto que se deben hacer correcciones para tomar en cuenta el grado de curvatura si lo hay, y por la distancia entre los platos de centro de las carretillas de cualquier carro que tenga que circular sobre la via. Ademas del marco dicho con sus brazos una de las carretillas esta conectada con un puntero marcador y su esfera de modo tal que marque directamente el grado de curvatura, mientras que un péndulo que puede girar libremente al traves del carro va conectado a otro puntero y esfera para indicar directamente la sobreelevacion (peralte) de cualquier carril.

**89. Carros de inspeccion y de mano.** Estos varian, en su construcción, desde simples plataformas con palancas de mano engranadas, hasta la combinación de carro y locomotora, usados por el personal directivo del ferrocarril. No obstante muchos de estos carros llevan ahora motores de gasolina : que si es verdad que requieren mas conocimiento para manejarlos, que los carros de mano, pueden alcanzar velocidades muy altas, y pueden generalmente mantenerse fuera de la via de los trenes. Algunos están construidos de tal modo que sus ruedas y ejes forman un circuito metálico que opera las señales automáticas y se protege asi de los trenes en movimiento en la misma via : pero muchos de ellos tienen las ruedas aisladas, y necesitan por consiguiente orden de via para circular.

**90. Carros registradores de via.** Vease este epigrafe en construcción de via y conservacion, pag. 896.

**91. Carros dinamómetros,** vease epigrafe Resistencia del Tren ¶ ¶ 56, etc. pag. 1139.

---

* *N. del T.* — Estos carros van, en verdad, a despejar la via. No sabiendo cómo se llaman en español, hemos resuelto llamarlos de « *despejo* ».

**92. En los equipos de auxilio** se tiene generalmente una poderosa grua de vapor montada en un carro, y cierto número de carros, que llevan un equipo variado con medios para comer y dormir. Llevan carriles, traviesas y partes de desvíos, tornillos surtidos, tuercas y tornillos; herramientas de muchas clases : equipo para izar aparejos, cadenas, sogas, cables, ganchos, bloques de madera, también luces portátiles potentes, extinguidores de incendio, hombres de linea con teléfono, botiquines, encarriladores, etc., etc.

**93. Encarriladores** son hechos en pares, y son piezas fundidas formadas de ranuras o pestañas de tal modo, que cuando se colocan sobre las traviesas y adyacente a los carriles, guian cada par de ruedas hacia los carriles a medida que el carro es empujado por la via. A menudo van provistos con tacos, para encajar, o para clavarlos en la traviesa, y ayudar a su fijacion.

**94. Tipos de carga.** Tal como están establecidos por la Asociacion de Maestros constructores de carros, se determinan en un folleto que puede obtenerse del Secretario en el Edificio Old Colony, Chicago Ill. El propósito es por supuesto, cargar los carros lo mas igual posible, para poder sostener la carga en su lugar, y tomar precauciones, cuando la carga ocupa mas de un carro teniendo en cuenta las curvas y desigualdades de la via. Cuando la carga es lo suficiente larga para dos o mas carros, puede soportarse en dos pivotes improvisados, uno en el frente y otro atras del carro. Si el material debe sostenerse por el medio, se provee de placas sostenedoras, de metal, que permitan un deslizamiento lateral fácil. Cuando se tengan que usar mas de dos carros, el carro extra generalmente no soporta peso y actúa simplemente como un separador. Algunas cargas que van en tres largos de carro, como vigas armadas de acero, etc., pueden cargarse completamente sobre el carro central, los otros dos son separadores. Las pilas de listones, barriles, tubos, tejas, etc., deben asegurarse adecuadamente en su lugar con amarres laterales y verticales.

# RESISTENCIAS EN LOS TRENES

## GENERALIDADES

**1. Las fuerzas** (o fuerzas componentes) que actúan sobre un tren en dirección paralela a la vía, pueden clasificarse como :
(a) fuerzas de « *impulso* »; tienden a poner en movimiento, a acelerar el tren;
(b) resistencias; tienden a detener o retardar el tren.

**2.** La fuerza de tracción de la locomotora, la gravedad, el viento, la inercia, pueden obrar como fuerzas de impulso (a) o como resistencias (b) según las circunstancias; pero la fricción (externa e interna), las curvas, y el aire en reposo producen necesariamente *resistencia* (b).

**3.** En cualquier caso dado, la resistencia del tren, $F$, es la suma de las resistencias que sobre él actúan.

**4.** La fuerza de tracción que el vapor trasmite por medio de la locomotora tiene que mover a ésta y al ténder, lo mismo que a los coches; pero frecuentemente se toma la « resistencia » como la de los coches solamente, o sea la que se opone a la tracción ejercida por la barra de tiro, detrás del ténder.

**5. Componentes de la resistencia de un tren.**

$F_n$ = res. normal = la res. total en una vía recta y a nivel; tren en reposo o a una velocidad uniforme, en aire en reposo, y a temperaturas normales; = la resistencia a que todo tren se halla necesariamente sometido;

$F_s$ = resistencia de las pendientes;
$F_c$ = resistencia de las curvas;
$F_w$ = resistencia del viento;
$F_i$ = resistencia de la inercia, debida a cambios de velocidad

} Resistencias incidentales.

Por tanto, para la resistencia total, tenemos :

$$F = F_n + F_s + F_c + F_w + F_i \ldots\ldots\ldots\ldots\ldots (1)$$

**6. Unidad de resistencia.** Supongamos que $W$ = al peso del tren. Entonces el cuociente, $f = F/W$, es la resistencia *por unidad de peso*, o la unidad de resistencia. De modo semejante, $f_1$, $f_2$, etc., representan respectivamente la resistencia de la unidad de pendiente, y la resistencia de la curva tomada por unidad. Cualquier resistencia puede ser expresada por una pendiente *equivalente*. Véase ¶ 33.

## RESISTENCIA NORMAL

**7.** La resistencia normal, $f_n$, es la resistencia, por unidad de peso, en una vía recta, a nivel, a una velocidad uniforme, en aire quieto. De la resistencia total, es esa la porción a que todo tren en movimiento se halla siempre sujeto. Para resistencias incidentales véase ¶ 31, etc.

### Componentes de la resistencia normal de un tren, $f_n$.

**8.** (a) fricción entre las cabezas del carril y las llantas y las pestañas de las ruedas;
(b) resistencia debida a la ondulación de la vía bajo un tren en movimiento;
(c) fricción interior de los coches y de la locomotora;
(d) resistencia del aire en reposo.

### Fricción entre las ruedas y las cabezas de carril.

**9.** Cuando las pestañas de las ruedas corren separadas de la cabeza de los carriles, tenemos, normalmente, entre los carriles y las llantas de las ruedas, tan sólo la fricción del mov sobre la vía (véase pág. 435, ¶ 193); y esto es de insignificante importancia cuando la vía y el material rodante se hallan en buena disposicion; pero la fricción por deslizamiento entre la cabeza del carril y las pestañas de la rueda, puede ser de considerable importancia, particularmente cuando hay oscilación o viento lateral (véase ¶ 44), y va a menudo acompañada del roce lateral de las llantas sobre las cabezas. En las curvas, los dos carriles son de diferentes longitudes, y tenemos una fricción longitudinal entre llanta y cabeza. Las condiciones varían tanto, en diferentes vias, y de un momento a otro en el mismo tren, que es imposible establecer preceptos útiles sobre este particular, ni sobre lo que sigue.

**10. La resistencia debida a las ondulaciones de la vía** bajo un tren en movimiento es, por supuesto, mayor sobre carriles y vias dúctiles.

**11. La fricción interna del material rodante** consiste principalmente (la de locomotoras en parte) en la fricción *en los muñones*. Su valor, en libras, por tonelada, es :

$$f_1 = 2000\ c\ d/D \qquad (2)$$

donde $c$ = al coeficiente de fricción del muñón girando en su muñonera, $d$ = al diámetro del muñón, y $D$ = al diámetro de la rueda. Esto supone $d/D$ constante; y en la práctica, puede de ordinario calcularse un valor (término medio) de $d/D$, para cada tren.

**12. Resistencias de rueda y muñón combinadas.** Es difícil determinar estas resistencias, independientemente de las otras resistencias normales. Los experimentos que se han hecho con ese fin no parecen ofrecer ninguna confianza. De los experimentos sobre cuestas, Wellington deducía de 4 a 6 libras por tonelada de 2.000 libras.

**13.** En las locomotoras (Am Loco Co., Bulletin 1.001, feb, 1910), la fricción de las ruedas motrices, pistones, válvulas, cabeceos, etc., se calcula en 22.2 libras por cada 2.000 libras de peso sobre las motrices. La *fricción* en los *muñones* de la locomotora, y de las ruedas del tènder, se considera igual a las de los coches.

**14. Resistencia del aire normal,** $F_1$. Resistencia con aire quieto. (Véase también resistencia del viento, $f_w$, ¶ 44). Los datos son contradictorios. El profesor W. F. M. Goss, *Western Ry Club Proces*, 1898, abril 25, página 347; relata experimentos hechos en una caja rectangular ancha y cerrada, en la cual las corrientes de aire de velocidades conocidas tropezaban directamente contra la extremidad del frente de trenes fijos de 1 a 25 coches modelo, de cerca de 3,5 pulg de ancho, 4,5 pulg de alto, 12 pulg de largo (8,89 × 11,43 × 30.48 cm) cada uno de ellos conectados por medio de un dinamómetro, a una base fija. El profesor Goss deriva las siguientes fórmulas, en las cuales supone que las dimensiones lineales del material rodante efectivo son 32 veces las de los modelos en cada dimension lineal; que los vagones de carga tienen 33 pies (10,06 m) de largo, y los de pasajeros 66 pies (20,12 m).

Supongamos que :

$F_h$ = a la resistencia atmosférica total, en lbs.;
$V$ = a la velocidad, en millas por hora;
$L$ = a la longitud, en pies, de cualquier tren, incluyendo la locomotora y el ténder;
$l$ = a la longitud, en pies, de cualquier tren, excluyendo la locomotora y el ténder;

luego, para el tren entero : $F_t = 0.0003\,(L + 347)\,V^2$..... (3)
para los coches solamente : $F_t = 0.0003\,(l + 53)\,V^2$..... (4)
para la loco y ténder : $F_t = 0.125\,V^2$..... (5)

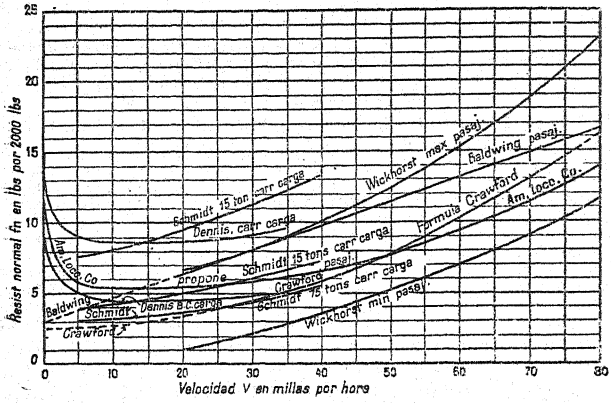

**Fig. 1.**

El profesor Goss considera que estas fórmulas dan resultados que no varían más de 15 a 20 por ciento de la verdad en la práctica.

Unidad de resistencia aérea, $f_a = F_a/W$, donde $W$ = al peso del tren en toneladas de 2.000 lbs.

**15.** Aumentan la resistencia aérea *los espacios entre coche y coche ;* las *puertas laterales abiertas*, y la *diferencia de altura en los vagones*, y tambien cuando en un mismo tren alternan furgones y plataformas. « Se pagan con carbón las desventajas y la tardanza en que se incurre al no poner juntos los furgones cerrados. Eso mismo permite al propio tiempo, al guardafreno moverse en el tren con mas rapidez. « (Angus Sinclair, en « Conducción y Manejo de locomotoras », 1891, pág. 375.).

**16. La resistencia aérea de frente de la locomotora** se calcula como de $0{,}002\,V^2A$; donde $V$ = vel., en millas por hora, $A$ = superficie transversal de la locomotora, generalmente calculada en 120 pies cuadrados (11,15 m²). Boletín 1.001, febrero de 1910, de la Cia Americana de Locomotoras.

## Factores que afectan la resistencia normal.

### Impulso inicial (salida).

**17.** Al arrancar el tren (véase figura 1), el valor de $f_n$ es mucho mayor que cuando está en marcha. La iniciación de la marcha puede ser facilitada retrocediendo lo bastante para aflojar los enganches, de modo que el tren arranque como si fuera carro por carro.

**18. A. C. Dennis,** Am. Soc. C. E. Trans., junio 1903, vol. 50, p. 1, encuentra que « después de que el tren se ha detenido por algún tiempo, las resistencias son de cerca de 2 lbs por tonelada sobre lo normal hasta que el tren ha corrido lo suficiente para que los muñones se calienten y se aceiten bien ».

**19. A. K. Shurtleff,** Am. Ry. Eng. & M. of W. Assn, Boletín 84, febrero de 1907, pág. 98, etc., opina que sobre la temperatura de congelación la mayoría de los trenes de carga puede echarse a andar, en una vía a nivel, con una fuerza de tracción de 13 lbs por tonelada de 2.000 lbs; pero una temperatura glacial, o un arranque descuidado, pueden aumentar esta proporción a 25 ó 30 libras por tonelada. En cambio, donde la parada es solo de un instante, los trenes arrancan con una fuerza en la barra de tracción de 6 lbs por tonelada.

**En marcha.**

**20. Efecto de la distancia recorrida.** A medida que la distancia recorrida aumenta, después de una parada, los muñones se calientan, es mejor su lubricación, y la resistencia disminuye en consecuencia. Durante la primera milla o dos, aun a velocidad uniforme y temperatura aerea constante, la resistencia normal, $f_n$, puede ascender hasta 50 % sobre el mínimo, que no se alcanza hasta que el tren lleva recorridas de 8 a 10 millas (14 a 16 km) en tiempo cálido, y alrededor de 35 millas (56 km) si hace frío. Con coches pesados y altas velocidades, la distancia requerida para alcanzar el mínimo $f_n$, es menor que con coches ligeros y bajas velocidades; pues el peso sobre las chumaceras y el aumento de velocidad ayudan a calentar aquellas y a licuar y distribuir bien el lubricante. (Prof. Eduardo C. Schmidt, Central Ry Club; Ry Age Gazette, enero 12 de 1912.)

**21. Aumento de velocidad,** fig. 1. La alta resistencia normal, experimentada al arrancar, disminuye muy rápidamente en cuanto la velocidad aumenta digamos en 5 millas por hora. De 5 o 10 (8 a 16 km) hasta 30 o 35 millas (48 a 56 km) por hora (velocidades usuales de los trenes de carga) $f_n$ aumenta ligeramente, y luego más rápidamente a medida que aumenta la velocidad.

La fig. 1 muestra las curvas de $f_n$ conforme a los experimentos y fórmulas que siguen :

## Experimentos.

**22. A. C. Dennis,** 1902. Am. Soc. C. E. Trans, 1903 junio, volumen 50, p. 1 Carrera total, más de 3.000 millas. Curvas *A* y *B-C*. Carreras emprendidas con :

(*A*), 105 furgones vacíos, vía sólida (frío), buen carril;
(*B*), 47 — cargados, vía sólida (frío), buen carril; neto/tara = 2.
(*C*), 52 — vía suave; neto/tara = 63/27.

Los resultados (*B*) y (*C*) son prácticamente idénticos.

**23.** Las resistencias (compensadas por los cambios de velocidad, véase ¶ ¶ 45-52) parecían ser mayores que las normales al aumentar la velocidad, y menores cuando disminuye. Mediante pruebas en cuestas, la resistencia de la locomotora, por unidad de peso, resultó ser casi igual a la de los carros *vacíos*.

**24. Max H. Wickhorst,** 1900, en el Ferrocarril de Chicago, Burlington Quincy, entre Chicago y Burlington, III (206 millas). Eng News, 1901, octubre 31. Cinco carreras, con vagón dinamómetro, 2 de equipaje y 2 de correo; tres carreras cargado, 180 toneladas, promedio 55 millas (88,5 km) por hora; dos carreras ligeras, 160 toneladas, promedio 27.5 millas por hora. Temperatura media, 70° Fahr (21,1 C); viento muy suave : muy numerosas observaciones. Las dos curvas muestran, respectivamente, los mínimos y los máximos aproximados.

**25. Prof Eduardo C. Schmidt,** 1910, Boletín de la Universidad de Illinois, vol. VI, n.° 39. Muy minuciosas pruebas de 32 trenes de carga ordinarios, con pesos de 747 a 2.908 toneladas por tren, y de 26 a 89 carros en cada tren, y con un promedio de cerca de 15 a 70 toneladas por carro; vía en buenas condiciones; temperatura atmosférica de 34° a 82° Fahr. (1,1 a 27,8 C). Véase tres curvas escogidas, figura 1; velocidades de 5 a 40 millas (8 a 64 km) por hora.

## Fórmulas.

**26. Cia Am. de Locom.** Boletín 1.001, feb. 1910, pág. 10; R. R. Age Gaz, 1909, sep. 10, p. 455 :

$$f_n = 5.4 + 0.002\ (V - 15)^2 + 100/(V + 2)^2 \ldots\ldots\ldots\ldots\ (6)$$

en la cual $V$ = velocidad en millas por hora *.

---

* (*N. del T.*) — Para convertir kilómetros en millas se multip. aquéllos por 0.621. Para conv millas en kilómetros se multip. las millas por 1.609.

**27. J. G. Crawford**, Eng. News, 1901, oct. 31. Basados en los experimentos hechos por Wickhorst en el Chicago, Burlington y Quincy, ¶ 24. Para velocidades entre 25 y 75 millas (40 y 121 km) por hora:

$$f_n = 2.5 + V^2/468 = 2.5 + 0.0021\ V^2 \ldots\ldots\ldots\ldots\ (7)$$

**28. Baldwin Locomotive Works**, fórmula de línea recta. R. R. Gaz 1899, marzo 17. Basada en experiencias hechas en la red de Filadelfia y Reading, entre Camden y Atlantic City, 55.5 millas (89,3 km) sin paradas.

$$f_n = 3 + V/6 = 3 + 0.167\ V \ldots\ldots\ldots\ldots\ (8)$$

## Tiempo Frío.

**29.** La Am. Loco. Co. (Boletín 1001, 1910, feb.) hace las siguientes reducciones del tonelaje arrastrado con temperaturas normales:

| Temperatura, Fahr. y C. | Deducción. |
|---|---|
| 45° a 25° (7.2 a − 3.9 C)..... | 8 por ciento. |
| 25° a 0° (− 3.9 a − 17.8 C)..... | 16 — |
| Bajo 0° (− 17.8 C)..... | 25 — |

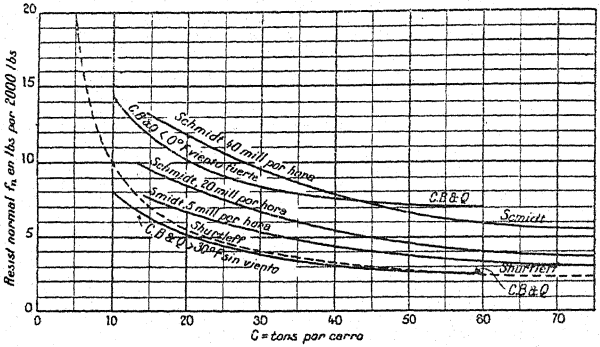

Fig. 2.

## Efecto del peso de los vagones.

**30. La fig. 2** muestra el efecto del peso de los vagones de carga, y de una manera incidental, hasta cierto punto, de la velocidad, sobre la resistencia normal, $f_n$; como sigue:

Experimentos en el C. B. & Q., R. R. Age Gazette, 1909, agosto 27, sep. 3;

Prof. Eduardo C. Schmidt, sus experimentos en el Illinois Central R. R. Véase también ¶ 25.

La curva de puntos representa la fórmula de A. K. Shurtleff, American Ry. Eng. & M. W. Assn., Boletín 84, febrero 1907, p. 99:

$$f_n = 1 + 90/C \ldots\ldots\ldots\ldots\ (9)$$

donde $C$ = peso medio del vagón cargado, en toneladas de 2.000 lbs. Esta fórmula está basada en experimentos hechos en dos redes ferroviarias. Total recorrido, más de 3,000 millas (4.828 km), 19 a 41 toneladas por vagón. La vía variaba desde «balasto con fango» con línea y superficies medianas hasta líneas de primera clase bien embalastadas con líneas y superficies buenas desde líneas en valles hasta líneas de montañas y en pendientes. Temperatura, de 0° a 60° Fahr (− 17.8 a 21.1 C).

## RESISTENCIA INCIDENTALES. Véase ¶ 5.

**31.** Además de la resistencia normal del tren, debemos ordinariamente tomar en cuenta las resistencias incidentales :

$F_p$, debida a las pendientes; $F_w$, debida al viento;
$F_c$, — las curvas; $F_i$, — a inercia.

### Resistencia debida a las pendientes.

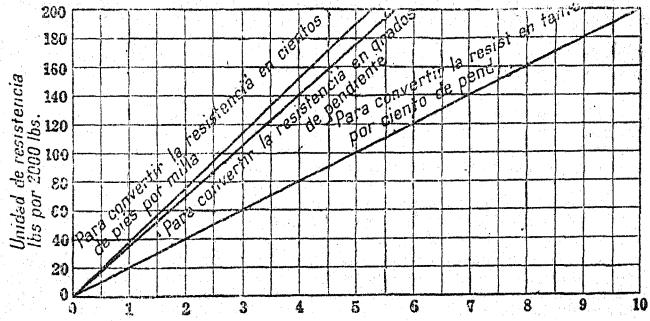
**32.** En toda pendiente, supóngase $a$ = al ángulo con la horizontal. Entonces, para la resistencia, paralela a la inclinación y necesaria para evitar el movimiento hacia abajo de un peso, $W$ ; tenemos :

$F_s = W \text{ sen } a$ ; y, como $f_s = F_s/W$ ; $f_s = \text{sen } a$..... (10)

Pero, con excepción de las lineas muy pendientes, la inclinación es tan ligera que, aproximadamente, sen $a$ = tang $a$. Por consiguiente, si $L$ = a la distancia horizontal entre dos puntos, y $h$ = a su diferencia de nivel, tenemos :

$F_s = W \text{ tang } a$, y $f_s = \text{tang } a = h/L$..... (11)

**33. La pendiente equivalente**, $s_e$, es la pendiente que produce la misma tendencia a lo largo de la vía que la debida a una resistencia dada; o bien la pendiente donde la tendencia a resbalar hacia abajo se halla precisamente equilibrada por la resistencia dada. En consecuencia, toda unidad de resistencia $f_s = F/W$, puede ser expresada como una pendiente. Para las varias conversiones, véase la fig. 3.



**Pendiente** (*Dada en tanto por ciento; pies (o bien metros por cien metros) por 100 pies; Cientos de pies por milla; o en Grados*).

**Fig. 3.**

**34. Unidades** de resistencia por la pendiente. Digamos :
$s$ = pendiente, en pies por cada 100 pies (uno por ciento = 1 %);
$S$ = pendiente, en pies por milla = 52.80 $s$.

**35.** Luego, por la **resistencia debida a la pendiente**, en lbiras por ton. de 2.000 lbs, tenemos :

$f_s = 20\ s = 0.3788\ S$..... (12)

y, por cualquiera unidad de resistencia $f$, debida a cualquier causa, tenemos :

**pendiente equivalente**, en pies por 100 pies = $f/20$..... ..... (13)

Pendientes reglamentarias; véase « Costo de Explotación », pag. 1156.
Pendiente de impulsión; véase pag 1149, ¶ 40.
Trabajo hecho y perdido en las pendientes; véase pag. 1147, ¶ 30.
Efecto de la longitud de la pendiente en la fuerza de tracción; véase pag. 1148, ¶ 37.

### Resistencia de las Curvas.

**36.** En cualquier punto de una curva, un eje, con ruedas cilíndricas fijas de diámetros iguales, tiende a rodar en dirección perpendicular a sí mismo y en una tangente con la línea central de la vía, conservándose paralelo consigo mismo.

Por consiguiente, la pestaña de la rueda exterior tiende a ejercer presión hacia afuera contra la cabeza del carril exterior, originando una fricción de deslizamiento entre los costados de la pestaña y de la cabeza del carril; y esta fricción se opone a la rotación de la rueda. Además, la cabeza del carril externo, mediante su reacción horizontal sobre la pestaña de la rueda, empuja la rueda externa (con su eje y la otra rueda) hacia el centro de la curva, compeliendo entrambas ruedas a resbalar lateralmente sobre sus respectivas cabezas de carril, causando así fricción de deslizamiento entre la cara de la rueda (llanta) y la superficie de la cabeza del carril. Esto, por supuesto, se combina (conforme a la resultante de los movimientos y las fuerzas) con cualquier resbalamiento longitudinal, y a medida que estos van ocurriendo; (¶ 37).

Todo esto acontece principalmente con las primeras ruedas de un vagón o tren. En las carretillas siguientes, la dirección de la tracción coincide, en cada carretilla o trole, con la cuerda de una porción de la curva; y así tiende a reducir la presión de dichos troles ulteriores contra el carril exterior.

**37.** Además, los ejes deben oscilar, en sentido horizontal, sacándolos de posiciones paralelas a ellas y haciéndolos entrar en posiciones más aproximadas a direcciones radiales a la curva; y esto exige que una rueda o la otra, o ambas ruedas resbalen longitudinalmente, a la vía. Véase también Corrugación, bajo el título de « vía » pag. 867, ¶ 91.

**38.** A fin de evitar o disminuir las resistencias así originadas, las caras de las ruedas se « hacen cónicas ». Véase Material rodante, pag. 1112, ¶ 11.

**39.** La resistencia, $F_c$, debida a las curvas está influenciada por muchas circunstancias; tales como el diámetro de las ruedas; la estrechez de la vía; la forma de la llanta de las ruedas (según sean más o menos cónicas), la longitud de las bases rígidas de las ruedas (véase ¶ 43), el sistema de acopladura, condición de la vía, elevación del carril externo (peralte), largo del tren (por lo que se refiere a la oblicuidad de tracción, véase fin del ¶ 36).

**40. Unidad de resistencia debida a las curvas.** Se considera generalmente que varía, — en igualdad de otras circunstancias, — en relación directa con la agudeza de la curvatura; es decir que, por resistencia de la curva, en libras por 2.000 lbs, en una curva de D° de agudeza, se tiene :

$$f = D\, f_1 \qquad (14)$$

donde $D$ = agudeza de la curvatura, en grados;
$f_1$ = resistencia de la curva, en libras por ton de 2.000 lbs, en una curva de 1° de agudeza.

**41. $f_1$ se calcula generalmente** que varía (según la naturaleza y las condiciones de la vía y del material rodante) entre 0.5 y 1.5 lbs por cada 2.000 lbs. Para compensar la curvatura, en las pendientes (véase pag. 1150, ¶ 51), es costumbre dar un margen entre 0.6 y 0.8 lbs por tonelada. Véase fig. 4.

**42. La fig. 4,** muestra la unidad de resistencia de las curvas, $f_c$, por Ec. (14), en varias unidades, que corresponde a las agudezas de 0° a 20°, y para valores de $f_1$, de 0.5 a 1.5. La línea radial punteada indica, en los diferentes grados de agudeza el desarrollo, en grados, de una milla de línea en curva de una agudeza dada; y la curva punteada indica los pies de línea por grado de desarrollo.

$$\text{Pies por grado de desarrollo} = 100/D \qquad (15)$$

$$\text{Grados de desarrollo por milla} = 5\,280\ D/100 \qquad (16)$$

Estos dos diagramas punteados representan las condiciones puramente geométricas, sin ocuparse de la *resistencia.*

**43. Efecto de la dimensión de la base de la rueda.** El prof. Wm. G. Raymond, en la Gaceta del F. C., (R. R. Gaz.), 1906, agosto 17, formula la resistencia en las curvas :

$$f_c = 0.4 + D\,(0.205 + 0.035\ B) \qquad (17)$$

donde $D$ = agudeza de la curva, en grados;
y $B$ = longitud de la base de la rueda, en pies.

**43 a. Efectos de la velocidad.** Es probable que la resistencia de la curva, $f_1$, por grado de agudeza (como res. norm.), varíe con la velocidad, en algo como lo indica la fig. 1. En otros términos, podemos esperar que sea (1) alta a velocidades muy bajas (porque el valor de la fricción se aproxima al de la fricción estática), (2) reducida a un mínimo a velocidades moderadas, y (3) aumentando, otra vez a altas velocidades.

### Resistencia del viento, $f_w$.

Para resistencia *normal*, $f_a$, debida al aire en reposo, véase ¶ 14.

**44.** Los vientos de frente se oponen por supuesto, — y los vientos en dirección contraria ayudan, — a los movimientos de avance de los trenes; y los vientos laterales, empujando las pestañas de la rueda contra la cabeza del carril, aumenta las resistencias; pero es poco lo que se sabe acerca de la importancia de estas influencias; y como su acción no puede ser verificada o prevista, su efecto es practicamente incalculable. Debe dejarse sin embargo un margen por tal concepto, según el criterio, al calcular la capacidad de las máquinas para mover cargas dadas en condiciones dadas. Donde la velocidad de los vientos de frente, o vientos de atrás pueden calcularse, la velocidad de viento puede agregarse o deducirse según corresponda, a la velocidad del tren y la suma o diferencia puede usarse en conexión con el ¶ 14. Por vientos « fuertes », la Am. Loco. Co. deduce un 8 % del tonelaje arrastrado con aire tranquilo, Boletín 1.001, feb. 1910. Véase también dos diagramas relativos al C., B. & Q., en la fig. 2.

### Inercia.

**45.** El acto de acelerar un tren exige una « fuerza de impulsión »; como el retardarlo requiere una resistencia. A la inversa, un tren que sufre aceleración puede decirse que presenta una resistencia, debida a la inercia; y uno que se retarda puede decirse que ejerce una fuerza, debida a la inercia. A fin de computar la resistencia total del tren, cuando se cambia la velocidad, hay que incluir la resistencia debida a la inercia. A fin de computar la resistencia total del tren, cuando se cambia la velocidad, hay que incluir la resistencia debida a la inercia; y para esto, es menester que sepamos o supongamos el peso, y (a) el grado de aceleración o (b) la velocidad, y la distancia dentro de la cual se realiza el cambio dado de velocidad.

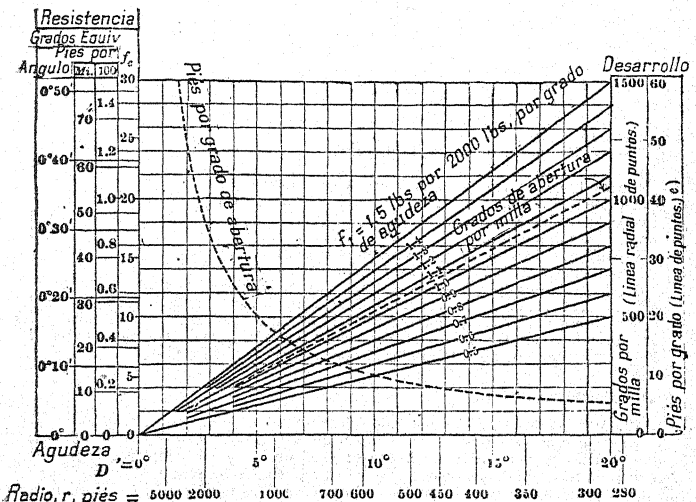


Fig. 4.

**46.** (a) Cuando un peso cae libremente, la aceleración de la velocidad, debida a la fuerza, $W$, de la gravedad, es $g = 32.2$ pies (9,81 m) por seg.; y la aceleración, $A$, de cualquier cuerpo, es directamente proporcional a la fuerza no equili-

brada $F_i$, que obra sobre él; o, $g/A = W/F_i$. Por tanto, para la fuerza o resistencia, $F_i$, debida a la inercia (y que produce aceleración o retardo), $A$, tenemos :

$$F_i = \frac{W}{g} A = M A \ldots\ldots\ldots\ldots\ldots\ldots \quad (18)$$

(b) Si un vagón se mueve en una vía horizontal, y :

donde : $M = W/g$ = a la masa del cuerpo.
$W$ = al peso del vagón; $M = W/g$ = masa del vagón;
$V$ = a la velocidad del vagón;
$F_i$ = a la fuerza hor. no equilibrada, que actúa sobre el vagón;
$L$ = a la dist y $T$ = al tiempo dentro del cual $F_i$ puede producir o destruir $V$;
$K$ = la energía cinética del vagón = $F_i L$ = al trabajo correspondiente.

Entonces (Mecánica, pág. 359, etc., Art. 19) :

$$K = M V^2/2 = F_i L \ldots\ldots\ldots\ldots\ldots\ldots \quad (19)$$

$$F_i = K/L = \frac{\frac{1}{2} M V^2}{\frac{1}{2} T V} = M \frac{V}{T} = M A \ldots\ldots\ldots\ldots \quad (20)$$

**47. Valores.** Lo siguiente puede tomarse como guía de la escala de aceleraciones, $A$, y de los valores de $fi$, que pueden esperarse en la práctica :

$A$ = aceleración en pies/seg en cada seg = 0.0161 $fi$;

$fi$ = fuerza en libras por 2.000 lbs = 62.1 $A$.

Aceleraciones de salida;

Pruebas de acelerómetro por Harry Egerton Wimperis, Inglaterra; Mins Proc Inst C. E., 1911-12, II Parte, lámina 8.

Trenes eléctricos de unidad múltiple, al salir de las estaciones.

| | $A$ | $fi$ |
|---|---|---|
| Promedio | 1.5 | 93.2 |
| Máximo | 2.5 | 155.3 |
| Tren de vapor | 0.5 | 31.0 |
| Una sola locomotora americana, pesada, que arrastre un tren compuesto tan solo de 2 vagones de pasajeros, puede esperarse que logre (hasta velocidades moderadas) | 1.0 | 62.1 |
| Retardo de freno; | | |
| Trenes eléctricos y de vapor, Inglaterra | 4.0 a 4.5 | 248.4 279.4 |
| Varios tipos de frenos neumáticos Westinghouse modernos de alta velocidad. Velocidades 25 a 50 millas (40 à 80 km) por hora, Ferroc. Pensylvania. | 3.0 | 186.3 |
| maxim (exactamente antes de detenerse) | 8.0 | 496.8 |
| Suponiendo el coeficiente de fricción, $c = 0.2$ lb/lb; $A = 2.000 \times 0.0161\ c = 32.2\ c = g\ c$; y dando por sentado que todos los frenos estén debidamente ajustados | 6.4 | 397.4 |

Con trenes muy livianos para el servicio de arrabales, donde son esenciales las altas aceleraciones, las fuerzas o resistencias necesarias para contrarrestar la inercia, pueden exceder mucho a todas las demás fuerzas o resistencias.

## Inercia de rotación.

**48.** Además de la inercia resultante del movimiento del vagón, en general, a lo largo de la vía, tenemos, en la rotación de ruedas y ejes, una inercia *adicional*, que resulta de su rotación únicamente; y, como la inercia lineal del vagón, esta inercia de rotación de las ruedas y los ejes produce una resistencia durante la aceleración, y una « fuerza de impulsion » durante el retardo. Tenemos que tomar aquí en cuenta el « radio de giro » (pag. 369) de las partes rotatorias. Este es menor que el radio de la llanta de la rueda.

Supóngase :

$R$ = radio de la llanta de la rueda; $r$ = radio de giro de las partes rotatorias;

$V$ = velocidad rectilínea del vagón; $v$ = velocidad rotativa del punto al extremo de $r$;

= velocidad rotatoria de un punto en la llanta de la rueda alrededor del eje de la rueda;

$A$ = aceleración correspondiente; $a$ = acel. rotat. corresp.;

$K$ = energía del vagón; $k$ = energ. rot. de las ruedas, etc.;

$F_i$ = fuerza hor., aplicada en, y normal al eje de la rueda, que produce $A$; $F_r$ = fuerza tangencial al extremo de $r$ que produce $a$;

$F_t$ = fuerza hor., en el eje, que produce $a$.

$W$ = peso del vagón; $w$ = peso de las partes rotativas;

$M$ = masa del vagón $= W/g$; $m$ = masa de las partes rotativas $= w/g$.

Luego (puesto que $V/v = A/a = R/r$) tenemos :

$$k = \tfrac{1}{2}\, m\, v^2\,; \qquad K = \tfrac{1}{2}\, M\, V^2\,; \qquad \frac{k}{K} = \frac{m\, v^2}{M\, V^2} = \frac{m\, r^2}{M\, R^2} = \frac{m}{M}\left(\frac{r}{k}\right)^2;$$

$$F_t = F_r\, \frac{r}{R} = m\, a\, \frac{r}{R}\,; \qquad F_i = M\, A\,; \qquad F_r = m\, a\,;$$

$$\frac{F_t}{F_i} = \frac{m\, a\, r}{M\, A\, R} = \frac{m\, r^2}{M\, R^2} = \frac{m}{M}\left(\frac{r}{R}\right)^2 = \frac{k}{K} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (21)$$

**49.** En virtud de quedar las masas de los ejes junto a sus ejes de rotación, su inercia rotatoria es tan insignificante que de ordinario es despreciada. Pero las ruedas de vagones y los motores eléctricos son de un peso y un diámetro considerables y su inercia rotatoria constituye una porción importante de la inercia total del vagón.

**50. Valores.** En ruedas de vagón ordinarias, $r/R$ ( $= v/V$), es generalmente alrededor de 0.7, variando algo con el dibujo de la rueda; y la relación, $w/W$, entre el peso, $w$, de las ruedas, y el peso total, $W$, del vagón y la carga, varía (principalmente de acuerdo con la cantidad de carga que el vagón contenga), generalmente entre 0.17 y 0.06.

De consiguiente $\dfrac{k}{K} = \dfrac{m\, r^2}{M\, R^2}$, puede esperarse que varíe de $0.7^2 \times 0.17$ a $0.7^2 \times 0.06$; es decir, de 0.085 a 0.03; o, como término medio, digamos $k/K = 0.05$: y $K + k = 1.05\ K$.

**51.** Como quedó determinado por la *Westinghouse Mfg. Co.*, y computado con datos proporcionados por la *General Electric Co.*, $k/K$, *en motores eléctricos*, varía entre límites muy amplios. En general, sin embargo, se calcula entre 0.05 y 0.15 en vagones de servicio urbano o interurbano, despreciando las ruedas y los engranajes, por los cuales, en semejantes vagones, $k/K$ parece valer alrededor de 0.10.

Con locomotoras eléctricas, la variación es mucho más amplia; ciertas locomotoras eléctricas sin engranajes, tienen $k/K$ menor que 0.10, incluyendo las ruedas; mientras que en otras locomotoras de carga de bajo engranaje, $k/K$ puede llegar hasta 0.60.

## Carga de velocidad.

**52.** Supongamos :

$H = V^2/2\, g$ = carga debida a la velocidad hor. del vagón;

$h = v^2/2\, g$ = carga debida a la velocidad curvilínea del punto al extremo del radio de giro, $r$.

Para una masa dada, $h/H = k/K$. Por consiguiente, tomando $k/K = 0.05$, o $K + k = 1.05\ K$, tendríamos :

$$H + h = 1.05\, H.$$

De la ec (20), ¶ 46, substituyendo $(K + k) = 1.05\ K$, por $K$, tenemos :

$F_i = 1.05\ K/L.$ Por tanto, $F_i = 1.05\ W\ H/L$ ; y :

$$f_i = \frac{2.000}{W} F_i = \frac{2.100\ H}{L} = \frac{2.100\ V^2}{2\ g\ L};$$

donde $V$ = velocidad hor. del vagón, en pies por sec. = $(1.466..) \times V\ m$;
donde $V m.$ = velocidad en millas por hora. Por consiguiente tenemos :

$$f_i = 70.15\ V\ m^2/L \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (22)$$

## SUMARIO

**53.** La fig. 5 da una idea general de las relaciones que existen entre la resistencia normal, $f_n$, y las tres resistencias incidentales calculables, $f_s$, $f_c$ y $f_i$, debidas a pendientes, a las curvas, y a aumentos de velocidad, respectivamente.

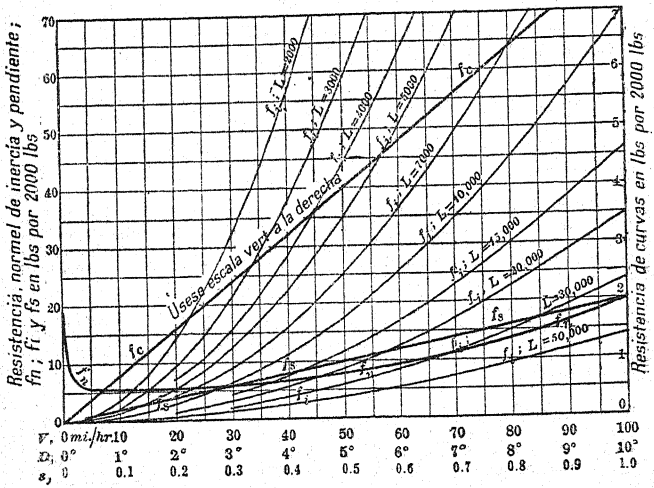

**Fig. 5.**

La escala $V$ se refiere solamente a los diagramas $f_n$, y $f_i$; mientras que las escalas $s$ y $D$ se refieren a los diagramas de $f_s$ y $f_c$ respectivamente.

Obsérvese que la escala vertical de la derecha se relaciona con el diagrama $f_c$ únicamente.

El diagrama $f_n$ representa la fórmula ec (6) ¶ 26 de la Am. Loco Co. :

$$f_n = 5.4 + 0.002\ (V - 15)^2 + \frac{100}{(V + 2)^2},$$

donde $V$ = velocidad en millas por hora.

El diagrama $f_s$ representa ec (12), ¶ 35,

$$f_s = 20\ s,$$

donde $s$ = pendiente en pies por 100 pies ó metros por 100 mets.

El diagrama $f_c$ representa ec (14), ¶ 40 :

$$f_c = D\ f_1,$$

donde $D$ = agudeza de la curva, y $f_1 = 0.8$.

**54.** Las diversas curvas $f_i$ representan la suma de las resistencias de inercia lineal y rotatoria, donde la suma = 1.05 × res. lineal, y $L$ = a la distancia, en pies, en la cual se efectúa el cambio de velocidad. Al usar estas curvas, es necesario deducir las dos resistencias, una por el movimiento inicial y otra por la velocidad final (cada cual por la distancia $L$ en cuestión). Luego, resistencia de inercia = *únicamente a la diferencia* entre estas dos resistencias, cada una de las cuales representa por sí solo la resistencia cuando una de las velocidades es *cero*.

$$f_i = 70.15\ Vm^2/L \ldots\ldots\ldots\ldots \text{ec. (22), ¶ 52}$$

**55. Ejemplo.** Supongamos que el peso, $W$, del tren sea 1.500 toneladas; que la pendiente ascendente o terraplen, $s$ = 0.05 pies por 100 pies; la agudeza de la curva, $D$ = 3°; y supongamos que la velocidad, $V$, sea aumentada, durante una distancia, $L$, de 10,000 pies, de 30 a 40 millas por hora (vel. media, 35 millas por hora).

Entonces, en la fig. 5, tenemos :

| | Lbs por tons. |
|---|---|
| Resistencia normal, $f_n$, Am. Loco Co. ($V$ = 35 millas por hora)... | 6.2 |
| — de la pendiente, $f_s$ (= 20 × 0.05)..... | 1.0 |
| — de la curva, $f_c$ (= 0.8 × 3)..... | 2.4 |
| — de la inercia, $f_i$ (= 11.2 − 6.3)..... | 4.9 |
| Unidad total de resistencia, $f$, ..... | 14.5 |

Resistencia total, $F = f\ W$ = 14.5 × 1.500 = 21,750 lbs.

De las cuales son debidas :

a resistencias con velocidad uniforme 9.6 × 1.500 = 14,400 lbs.

a resistencias por aumento de velocidad 4.9 × 1.500 = 7,350 lbs.

## VAGONES DE DINAMÓMETRO

**56. La función principal** de un vagón de dinamómetro es el de medir (y registrar) la *fuerza de arrastre o tracción*. El vagón dinamómetro se coloca entre el ténder de la locomotora y el primer coche o furgón del tren, y la suma del arrastre de la barra de tracción indica entonces el esfuerzo de tracción ejercido sobre el tren con exclusión del ténder.

**57. Contador o registro.** El vagón se halla de ordinario dotado de aparatos destinados a registrar o trazar los diversos detalles que habían de obtenerse. Este aparato consiste esencialmente de una mesa o marco ancho, colocado en el vagón, con una larga y continua banda o tira de papel que va registrando los datos. Esta banda se mueve longitudinalmente sobre la mesa y bajo numerosos lápices o plumas, cada uno de los cuales es susceptible de mayor o menor movimiento lateral a través del papel.

**El movimiento del papel,** podrá hacerse proporcional a la distancia recorrida a lo largo de la vía, o al tiempo consumido. Si el movimiento del papel ha de ser proporcional a la distancia recorrida, el carrete donde va envuelto el papel, o que lo guía, va generalmente encajado en un eje; dejándolo sin encajar, toda vez que la acción del freno pueda hacer que las ruedas se resbalen. Es preferible arreglar este encaje de modo que el papel se mueva en una sola dirección, sea que el vagón avance o retroceda, pues de otro modo las inscripciones se sobrepondrían al retroceder y volver a arrancar el tren. Si se quiere que el movimiento del papel sea proporcional al *tiempo*, el carrete o tambor puede ser movido mediante un mecanismo de relojería, o por medio de un mecanismo en abanico bien construído o si no, con magnetos movidos por contactos operados a cortos intervalos por un sistema de relojería.

**58. Plumas.** Los movimientos laterales de los diversos lápices y plumas se gobiernan, unas veces por medio de magnetos eléctricos, y otras valiéndose de correspondencias mecánicas de varias clases, según las necesidades.

**59. La fuerza de tracción de la barra de tiro,** se medía en otros tiempos por medio de un mecanismo semejante al de las básculas, puesto a un costado, de manera que mida las fuerzas horizontales en vez de las verticales. Es costumbre general ahora, sin embargo, conectar la barra de tiro directamente con un émbolo

que se desliza en un sólido cilindro que contenga aceite. Hay un tubo que va de este cilindro a un cilindro menor colocado en el aparato registrador, y dotado de un émbolo y un resorte, como en los « indicadores » ordinarios de máquinas de vapor. Entonces este registra, así, directamente sobre el papel, moviendo su pluma más o menos de un lado, según la intensidad de la fuerza trasmitida a través del aceite, desde la barra de tracción. Por otro método se hace de la barra de tiro un « indicador » de cilindro principal, ajustándolo con resortes ó muelles precisos, pero pesados, y transmitiendo directamente su movimiento mecánicamente a la pluma del registrador. Al usar ambos métodos deberá compensarse el escape de aceite a causa del paso del émbolo en el cilindro. Esto se hace generalmente valiéndose de una bomba especial.

**60. Aceleración.** Los acelerómetros dependen ordinariamente de la desviación hacia adelante o hacia atrás de un péndulo u otra masa excéntricamente suspendida, bajo la acción de la fuerza resultante de la aceleración o del retardo. Se ha experimentado alguna dificultad en evitar las oscilaciones violentas y engañosas que producen indebidamente retardo en el movimiento. El acelerómetro de Wimperies (*Mins.* Proc. Inst. C. E. (Inglaterra), 1911-12, Parte II, página 420), parece dar buenos resultados, amortiguando los movimientos de las masas magnéticamente. Wilfredo Lewis de Filadelfia ha empleado un instrumento parecido al tubo nivelador corriente; y la marcha o funcionamiento de la ampolla parece pasablemente satisfactorio; pero este artificio no registra. Otro instrumento, con que ha hecho experimentos la Compañía Trautwine, no puede sobreindicar, por repentinos que sean los cambios de fuerza aceleradora. El aparato (transportado en el vagón), depende de la caída constante de una corriente de partículas, tales como arena, bolitas de acero, o gotas de agua, desde un punto dado del aparato, y desde determinada altura, sobre una báscula colocada en el fondo del aparato y colocada en la dirección en que la aceleración ha de medirse. Las partículas caerán en rápida sucesión, y cada una de ellas, cayendo libremente, deberá continuar cayendo con la velocidad horizontal que tenía al ser soltada. Por consiguiente, cualquier cambio de velocidad del vagón ocurrido durante la caída de cualquiera de las partículas, remueve más o menos la báscula que está debajo, de modo que la partícula cae sobre la báscula a una distancia mayor o menor del cero (que se halla inmediatamente debajo del punto desde donde las partículas se sueltan), en proporción directa a la aceleración media durante el lapso de la caída.

**61.** Estrictamente hablando, un acelerómetro puede medir la aceleración *únicamente* si *se corre a nivel.* Con el tren en una *pendiente*, el efecto de la pendiente aumenta o disminuye las indicaciones, y, a menos que se puedan hacer correcciones, en este sentido, las indicaciones de las aceleraciones son engañosas. En un vagón o tren que corra sin fuerza motriz ni frenos (en cualquier pendiente), las indicaciones de un acelerómetro dan entonces la medida de la resistencia total del vagón, o del tren, en conjunto.

**62. Las fuerzas laterales,** debidas a las curvas o a desigualdades de la vía, son frecuentemente medidas por un acelerómetro colocado a ángulos rectos con la vía, particularmente en los vagones de prueba.

**63. El tiempo** deberá registrarse cuando el movimiento del papel está en proporción con la distancia recorrida; y una indicación de tiempo es útil aun cuando el papel se mueva a intervalos de tiempo. Esto se realiza generalmente con una pluma que se desvía por medio de un electromagneto accionado cada cinco segundos mediante contactos con un reloj.

**64. La distancia** deberá registrarse si el papel se hace correr en proporción con el tiempo, y una indicación de distancia es útil aun cuando el papel se mueva en proporción a *la distancia.* Se hace con una pluma desviada por medio de un electromagneto, o mediante engranaje con las ruedas, cada vez que se haya recorrido cierta distancia. En todo caso, la distancia se registra generalmente también por un vigilante sirviéndose de un botón de presión, mediante el cual puede desviar otra pluma al pasar cada poste de milla u otro objeto.

**65. Velocidad.** La velocidad puede deducirse de los *records* de distancia si el papel se mueve en proporción dada del tiempo, o *viceversa.* Sin embargo, se la traza con preferencia con una pluma especial que, a medida que la velocidad cambia

va desviándose de su línea mediante una correspondencia mecánica con un aparato semejante a una palanca centrífuga, o por algún otro sistema de medidor de velocidad; tambien puede arreglarse la pluma de manera que sea desviada de su línea por medio de un contacto eléctrico o engranaje con las ruedas, a intervalos proporcionales a la distancia recorrida, soltándola al término de intervalos de tiempo dados, para dejarla que vuelva a la línea de partida, obteniendo así un *record* de velocidades medias a cortos intervalos sucesivos de tiempo. Usando de un mejoramiento adicional solamente el mecanismo contador o de marcha ascendente regresa a cero, en tanto que la pluma permanece en el punto anteriormente alcanzado, trazando por consiguiente una curva en vez de una serie de ordenadas.

**66. La acción del freno neumático** se registra generalmente por medio de un émbolo en un cilindro pequeño conectado con el cilindro del freno del vagón.

**67. La presión de la caldera** se ha registrado de modo semejante, valiéndose de un tubo de vapor conectado con la locomotora.

**68. Velocidad del viento.** — Esta ha sido registrada (al menos en el vagón de pruebas de la Universidad de Illinois) con el anemómetro Robinson en forma de copa que ordinariamente se usa en la Oficina de Señales Meteorológicas, produciendo y rompiendo el contacto eléctrico cada 0.2 milla de viento.

**69. Dirección del viento** : ésta se registra (en el mismo vagón) por medio de una conexión mecánica con una veleta neumática por la cual la desviación de la pluma se conserva = al seno del ángulo de la veleta, derecha o izquierda, mientras que la posición de avance o retroceso de la veleta es indicada por otra pluma.

**70. Las curvas** pueden registrarse por una conexión mecánica con una de las carretillas o troles del vagón.

**71. Los datos mixtos o diversos** son registrados las más veces a mano, por medio de botones de presion colocados en el vagón o en la locomotora; este método se emplea cuando se trata de medir las paladas de carbón que se ponen en el hogar de una locomotora; cuando se abren y cierran las puertas de éste; cuando se abre y cierra la válvula de paso, para la posición de la palanca de contravapor, etc., etc.

# DINÁMICA DE LOS TRENES

## GENERALIDADES

### Fuerza de tracción, Resistencias, Velocidad, Energía.

**1.** Los movimientos de un tren se rigen por la relación que existe entre la fuerza de tracción y las resistencias. Esta relación se halla parcialmente bajo el gobierno del maquinista. Véase ¶ 4.

**2. Fuerza de tracción.** La fuerza de arrastre de una locomotora (pag. 1128) aumenta a medida que entra mas vapor en los cilindros (como cuando se aumenta el rendimiento de la caldera o la abertura de la válvula de paso, o se retarda la acción del cortavapor), y aumentando la « adhesión » entre las ruedas motrices y los carriles (como cuando se riega arena en ellos). La fuerza de tracción se disminuye reduciendo el vapor en los cilindros y por el fácil deslizamiento entre motrices y carriles.

**3. La resistencia** se aumenta aplicando los frenos o invirtiendo las máquinas de la locomotora; y se disminuye soltando los frenos.

**4. En la práctica**, no obstante, estas operaciones suelen complicarse con otros fenómenos. Así, un positivo *aumento de velocidad* (como el que resulta de admitir más vapor en los cilindros) aumenta la dificultad en mantener los aumentos de presión de los cilindros; en cambio, a medida que *el tren disminuye su marcha* se va facilitando más y más el mantenimiento de las expresadas presiones.

**5.** Además, en ciertas condiciones (Resistencia, páginas 1129, etc.) la resistencia atmosférica y la resistencia de fricción aumentan si se aumenta la velocidad. Como resultado de esto, cada pendiente tiene su límite de velocidad, que un tren en descenso y a su propio impulso no puede exceder. Véanse pág. 1159-60, ¶¶ 37-38.

### Efecto de la inercia.

**6. Energía.** Al aumentar la velocidad se almacena energía dinámica en el tren, y tal acumulación (salvo cuando la produce un movimiento en pendiente hacia abajo) exige un trabajo adicional de la locomotora. Al ir disminuyendo la velocidad, la energía motriz, acumulada ya en el tren, coopera en el movimiento de avance.

**7.** Para todo cambio de velocidad, como de $v_1$ a $v_2$, el cambio, en energía motriz, es

$$W \frac{v_1^2 - v_2^2}{2g} = m \frac{v_1^2 - v_2^2}{2} \text{ ; donde :}$$

$W$ = al peso, y $m$ = la masa, del tren; y $g$ = aceleración de gravedad = digamos, a 32.2 pies (9.81 m) por sec en cada seg.

**8. La altura de caida** = a la altura de la cual un cuerpo debe caer, para cambiar su velocidad de $v_1$ a $v_2$, es :

$$h_v = \frac{v_1^2 - v_2^2}{2g}. \text{ Por consiguiente,}$$

$$\text{Cambio en la energía motriz} = W \frac{v_1^2 - v_2^2}{2g} = W\ h_v.$$

Donde si $v_1$ o $v_2$ = cero, tenemos, velocidad = $v$, y cambio de energía = $W\ v^2/2\ g$ = $W\ h_v$.

## PENDIENTES

**9.** Cuando se trata de establecer las pendientes, es de vital importancia *su efecto sobre las velocidades del tren.*

### Perfil virtual.

**10. Altura de caida virtual; pendiente virtual; perfil virtual.** En las figuras 1 *a*, 1 *b* y 1 *c*, supóngase que *A B C... G* sea el perfil de un ferrocarril dado; y en cada fig., supóngase que un tren, viniendo de la izquierda, llega a *A* con una velocidad de *v* pies por seg. Imaginemos que *A a* representa en la escala del perfil efectivo, la altura de caida correspondiente, $h_v = v^2/2\,g$. Para mayor simplicidad, despreciamos aquí la velocidad rotativa de las ruedas; véase pag. 1136. En otros puntos, de ambas figuras, establezcánse los ordenados, *B b*, *C c*, *D d*, etc., que representan, según la misma escala, las alturas de caida en esos puntos, respectivamente. Luego, por lo que hace a las condiciones de estos perfiles, véase ¶ 13; en cualquiera de las figuras, *a b c... g* es el perfil virtual que corresponde al efectivo, *A B C... G*.

**11.** Supóngase que :

| | | |
|---|---|---|
| $T$ = la fuerza de arrastre (tracción) de la locomotora..... | paralela a la vía. | |
| $F$ = la resistencia total o resultante..... | — | — |
| $t = T - F$ = la fuerza resultante..... | — | — |
| = la fuerza que produce la aceleración..... | — | — |
| $F_g$ = la componente de la gravedad..... | — | — |
| $F_r$ = la resistencia que no obra..... | — | — |
| (« + » = a favor $T$ ; « − » = contra $T$)..... | — | — |
| $W$ = peso del tren..... | obrando verticalmente | hacia abajo. |
| $g$ = aceleracion debida a la gravedad... | — | — |

**12.** Como será demostrado, la marcha del tren se gobierna mediante la concordancia (que en parte depende de la dirección del maquinista) entre $T, F, F_g$ y $F_r$.

| Si $T$ es | $F_g$ es | $T + F$ es | $F_r$ es | $F =$ | $t\ (= T - F) =$ |
|---|---|---|---|---|---|
| $< F_g$ | − | − | + | $F_g - F_r$ | $T - (F_g - F_r)$ |
| | | | | | $= T - F_g + F_r$ |
| $> F_g$ | − | + | − | $F_g + F_r$ | $T - (F_g + F_r)$ |
| | | | | | $= T - F_g - F_r$ |
| → | 0 | + | − | $F_r$ | $T - F_r$ |
| ↘ | + | + | − | $F_r - F_g$ | $T - (F_r - F_g)$ |
| | | | | | $= T + F_g - F_r$ |

**13. Las figuras 1 a, 1 b y 1 c** representan tres casos típicos, y supuestos como sigue :

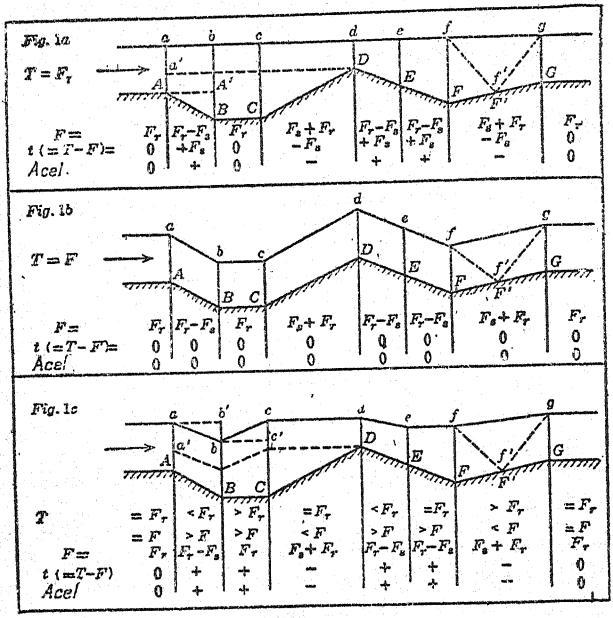
Fig. 1*a*. $T = F_r$. Perfil virtual horizontal;
Fig. 1*b*. $T = F$. Perfil virtual paralelo al perfil real;
Fig. 1*c*. Ninguna de las dos condiciones anteriores satisfecha.

**14. Fig. 1 a. « Tren sin fricción ».** Vamos a suponer ahora que la fuerza de tracción o arrastre en todo el tren se mantiene igual a la resistencia que no obra; o bien $T = F_r$. El tren se halla entonces mecánicamente en la condición de un cuerpo libre de toda fricción; es decir, todos los cambios de velocidad son los debidos a la gravedad solamente.

**15.** Luego, pasando de *A* a *B*, el tren pierde *A' B* en elevación, pero gana una suma igual en la altura de caida debido al aumento de velocidad, haciendo su alt de caida total, en *B*, $h_v = B\,b = B\,A' + A'\,b$. Por consiguiente, el perfil virtual, *a b*, entre *A* y *B*, es horizontal, como lo es también (en la fig. 1 *a*) el perfil virtual,

*a b c... g*, en la línea entera, *A B C... G*, suponiendo (como arriba) que $T$ y $F_r$ se mantengan iguales. Esto puede suceder, al menos aproximadamente, en los trenes ligeros y rápidos de pasajeros en pendientes cortas y moderadas. Tal condición continuaría existiendo indefinidamente (suponiendo que $T$ se mantenga $= F_r$), con la excepción de que si, en cualquier punto, la pendiente en cuestión, *A... G*, asciende al nivel *a... g* el tren se para, y no puede volver a arrancar sin un aumento de $T$ sobre $F$. Véase ¶ 21.

**16. Fig. 1 b. Velocidad uniforme.** Si la fuerza de tracción se mantiene igual a la resistencia total (que incluye la componente debida a la gravedad), es decir, si $T = F = \pm F_r \pm F_s$; de modo que $t = T - F =$ cero; entonces la velocidad (y por consiguiente la alt de caída, $h$, representada por *A a*, *B b*, etc.) permanece constante, e igual a la del tren al llegar a *A*; y cada tramo o extensión, *a b*,



Figs. 1.

*b c*, etc., del perfil virtual, *a b c... g* es paralelo al tramo correspondiente, *A B*, *B C*, etc., del perfil real, *A B C... G*. En tramos *a nivel*, como *B C*, tenemos $F_s =$ cero, $F = F_r$, y, en la fig. 1 *b* (como en toda la fig. 1 *a*), $T = F_r$, y *b c* horizontal.

**17. Fig. 1 c. Caso común.** En general (y especialmente con trenes de carga, pesados) la relación entre $T$, $F_s$, $F_r$ y $F$, *graduada* por el maquinista (véase ¶ ¶ 1, 2, 3) con arreglo a las condiciones existentes, no llena ni los requisitos de la fig. 1 *a* ni las de la fig. 1 *b*.

**18.** En el supuesto caso, representado por la fig. 1 *c*, tenemos :

En la fig. 1 *c*.

| Sección. | Pendiente real. | Pendiente virtual. | Fuerza de tracción, $T$. | Pendientes reales y virtuales. | $t\ (= T - F)$ y aceleración. |
|---|---|---|---|---|---|
| ..... *A* | → | → | $= F_r = F$ | *Paralelo* | 0 |
| *A* — *B* | ↘ | ↘ | $< F_r > F$* | *divergente* | + |
| *B* — *C* | → | ↗ | $> F_r > F$ | " | + |
| *C* — *D* | ↗ | → | $= F_r < F$ | *convergente* | — |
| *D* — *E* | ↘ | ↘ | $< F_r > F$* | *divergente* | + |
| *E* — *F* | ↘ | → | $= F_r > F$ | " | + |
| *F* — *G* | ↗ | ↗ | $> F_r < F$ | *Convergente* | — |
| *G* .... | → | → | $= F_r = F$ | *Paralelo* | 0 |

En general; figs 1 *a*, 1 *b*, 1 *c*,

| Si la pendiente virtual es : | La fuerza de tracción, $T$, es : | Si las pendientes virtual y real son : | La velocidad es : |
|---|---|---|---|
| en subida, | $> F_r$ | divergentes, | acelerada. |
| a nivel, | $= F_r$ | paralela, | uniforme. |
| en bajada. | $< F_r$ | convergente, | retardada. |
| | | coincidente, | cero. |

**19. El perfil de puntos**, *f f' g*, en cada una de las tres figuras, representa un caso donde, en lugar de proceder continuadamente de *F* a *G*, el tren se detiene, como en *F'* ; es decir, el caso en que la velocidad se reduce a cero, y las dos pendientes coinciden.

**20. Perfiles diferentes** *para trenes diferentes.* Puesto que los trenes difieren en cuanto a velocidad, etc., cada tren requiere separadamente su propio perfil virtual; así, la fig. 1 *a* representa aproximadamente las condiciones probables para trenes rápidos de pasajeros; la fig. 1 *c* las de trenes de carga, etc.

**21.** El perfil virtual muestra las velocidades, y los cambios de velocidad, que pueden esperarse de un tren dado en un perfil dado. Así : fig. 1 *a* o 1 *c*, si, en *A*, la velocidad fuera tal que la altura de caída fuera tan solo *A a'*, el tren se atascaría en *D* siempre que las demás condiciones permanezcan como queda indicado; pues el perfil virtual, *a d*, en ese caso desciende verticalmente y paralelo, a sí mismo en la distancia *a a'* = *d D*. Véase ¶ 15.

* En una pendiente de descenso, la resistencia *total* se convierte en *Fr* menos *Fs* (véase ¶ 12); y puede por tanto ser muy pequeña, ó cero, ó una cantidad negativa. Por consiguiente, la fuerza de tracción de la locomotora, *T*, aun siendo menor que *Fr*, puede aun ser mayor que la resistencia « total », *F*.

**22. Altura da caída ganada.** Fig. 1 *c*. En cualquier distancia dada, como *B C*, la alt de caida ganada que no obra, $h_v$ (o la alt de caida perdida segun el caso), representada por *c' c*, es directamente proporcional a la fuerza no equilibrada que no obra $t_r$ ($= T - F_r$ o $F_r - T$), obrando sobre el tren en toda esa distancia; y la proporción, entre dicha fuerza no equilibrada, $t$, y el peso del tren, $W$, es igual a la relación entre $h_v$ y la distancia, $L$, representada por *B C*. En otros términos,

$$\frac{t_r}{W} = \frac{h_v}{L}; \text{ o } t_r = W \frac{h_v}{L}.$$

**23. Las pendientes del perfil miden el exceso de fuerza.** Fig. 1 *c*. De un modo semejante, en la distancia, representada por *A B*, hay un exceso ($= t_r = F_r - T$) de resistencia que no obra sobre la fuerza de tracción ; y el aumento de velocidad y de altura de caida es en consecuencia menor, en la figura 1 *c*, que en la misma extensión, *A B*, en la fig. 1 *a*, donde $T = F_r$. La pérdida correspondiente, $h_r$, de velocidad inicial, en *A B*, fig. 1 *c*, comparada con la de la fig. 1 *a*, se halla representada por *b' b*. Aquí también :

$$t_r = W \frac{h_v}{L}.$$

La pendiente de las líneas en el perfil virtual dan pues la medida del exceso de la fuerza de tracción sobre la resistencia que no obra ó viceversa.

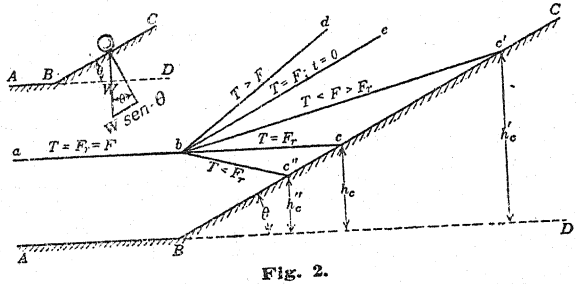


**Fig. 2.**

## Altura a la cual un tren subirá por una pendiente.

**24. Fig. 2.** Supóngase que un tren corre, a velocidad uniforme, sobre una vía a nivel, *A B*. Entonces (siendo uniforme la velocidad), tenemos, **en A B, T = F**; o bien, $t\ (= T - F)$ = cero (¶ 18); y (con *A B* estando a nivel), tenemos : componente de la gravedad, $F_s$ = cero; y fuerza de tracción, $T\ (= F) = F_r + F_s = F_r + 0$ = la resistencia que no obra, $F_r$.

**25. En B**, supongamos que el tren encuentra una subida, *B C* ; y supongamos
$\theta$ = al ángulo, *C B D*, entre la pendiente, *B C*, y la horizontal;
$t = T - F$ = fuerza neta de tracción.
= fuerza de tracción de la loco menos la resistencia total o resultante.
$W$ = peso del tren y la locomotora;
$F_s = W$ sen $\theta$ = a la componente de la gravedad;
$g$ = aceleración de la gravedad = 32.2 pies (9.81 m) por sec en cada seg;
$v$ = velocidad del tren en *B*.

**26. Y si, en la pendiente, B C** (a pesar de que $F_s$ se agrega, a la resistencia) $T$ es mantenida de modo que tengamos :
**T > F** (la pendiente virtual, *b d*, es *divergente* de la pendiente real, *B C*), entonces (véase ¶ 18) la velocidad es acelerada, y la aceleración = $g\ t/W$.

Si :

$\mathbf{T} = \mathbf{F}$, $t = 0$ (pendiente virtual, $b\ e$, paralela a la pendiente real ó efectiva, $B\ C$), entonces la velocidad es uniforme (aceleración $= g\ t/W =$ cero). En cualquiera de estos casos, el tren asciende la pendiente indefinidamente.

**27.** Pero si, en la pendiente, $B\ C$, tenemos :

$\mathbf{T} < \mathbf{F}$ (la pend virtual $b\ e$, $b\ e'$, o, $b\ e''$, y la pend. real, $B\ C$, convergen), entonces. la velocidad es retardada, con aceleración negativa $= -\ g\ t/W$, y la fuerza retardatriz no equilibrada, $-\ t = T - F$, llegará a detener el tren :

á una altura, $h_e$, $h_e'$ o $h_e''$, y

á una distancia, $h_e/\text{sen}\ \theta$, ó $h_e'/\text{sen}\ \theta$, ó $h_e''/\text{sen}\ \theta$ determinadas como sigue :

**28.** (1) Si, en la pendiente, $B\ C$, tenemos :

$\mathbf{T}\ (< \mathbf{F}) = \mathbf{F}_r$ (pend. virt., $b\ e$, *horizontal*),

entonces el tren (véase ¶ 14) se mueve bajo la acción de la componente de la gravedad, $t = F_s = W$ sen $\theta$, sola, con aceleración negativa $= -\ g\ t/W = -\ g\ W$ sen $\theta/W = -\ g$ sen $\theta$. Por consiguiente, la fuerza retardatriz no equilibrada, $-\ t = F_s = W$ sin $\theta$, llegará a parar el tren.

á una altura, $h_e = v^2/2g$, y

á una distancia, $B\ e = h/\text{sin}\ \theta$.

**29.** (2) Pero si, en la pendiente, $B\ C$, tenemos :

(a) $\mathbf{T}\ (< \mathbf{F}) > \mathbf{F}_r$ (pend. virtual, $b\ e'$, ascendente), o

(b) $\mathbf{T}\ (< \mathbf{F}) < \mathbf{F}$ ( — $b\ e''$, descendente):

entonces la fuerza retardatriz no equilibrada, $-\ t = T - F$ llegará a parar el tren

á una altura, (a) $h_e' = h_e\ W$ sin $\theta/t'$, o

(b) $h_e'' = h_e\ W$ sin $\theta/t''$ ;

á una distancia, (a) $B\ e' = h_e\ W/t' = h_e'/\text{sin}\ \theta$; o

(b) $B\ e'' = h_e\ W/t'' = h_e''/\text{sin}\ \theta$.

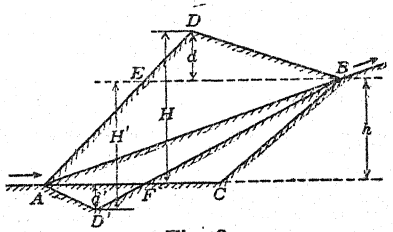

**Fig. 3.**

## Trabajo que resulta de las diferencias de alturas.

**30. Fig. 3. Teoría.** Al mover un tren, de peso, $W$, de $A$ a $B$ (sea por la pendiente uniforme, $A - B$, o por la vía $A - C - B$, o $A - D - B$, o $A - D - B$), el trabajo neto o resultante hecho debido a la diferencia de elevación, solamente, y despreciando la fricción, es teóricamente $W\ h$, es decir el trabajo de levantar el peso, $W$, a la altura vertical $h$.

**31.** Al atravesar $A - B$, o $A - C - B$, el tren no sube más allá de $B$, o desciende bajo $A$ ; y el trabajo *total*, debido a diferencia de elevación, es igual al trabajo *neto, resultante*, $W\ h$.

**32.** Al moverse por $A - D - B$ ó $A - D' - B$, el peso del tren, $W$ debe en efecto ser elevado a una altura mayor, $H$ o $H'$, respectivamente, haciendo el trabajo total debido a la diferencia de elevación $= W\ H$, o $W\ H'$, respectivamente; pero teóricamente, el trabajo adicional, $W\ d$ o $W\ d'$, debido a la elevación, $d = H - h$, o $d' = H' - h$, respectivamente, es compensado por el que realiza el tren cuesta abajo, después de trasponer la cumbre, $D$, o antes de alcanzar el punto más bajo, $D'$.

**33. Práctica.** Por tanto, el trabajo resultante, debido á la diferencia de nivel, queda, mecánicamente = $W\ h$; y esto se realiza con frecuencia, con más o menos aproximación, en la práctica; y la energía, debida a los descensos, se utiliza en una extensión que depende de las longitudes y de lo fuerte de las pendientes, y de las resistencias en ellas; dependiendo también de la pendiente posterior a $B$, y de si hay una parada en $B$ o al pie ($D'$) de la pendiente en bajada.

**34.** Toda subida, $E - D$ (o descenso, $A - D'$), que requiere un trabajo mayor que $W\ h$, va acompañada de un descenso, $D - B$ (o subida, $D' - F$) de igual altura vertical. Pero la « subida y bajada », en $E - D - B$ ($A - D' - F$) es $d$ ($d'$); y no 2 $d$ (2 $d'$).

## Consideraciones prácticas.

**35. Las pendientes aumentan el costo de explotación.**

En la subida de una pendiente, $A\ B$ o $C\ B$, fig. 3, pag. 1147, el ascenso, $h$, implica un gasto adicional de combustible. Reduciendo la velocidad, en la pendiente, se disminuirá la normal resistencia total (compárese la fig. 1 relativa a Resistencia del Tren, pág. 1130); pero la reducción de velocidad significa tiempo perdido y por consiguiente un aumento en el costo de la explotación.

**36. Pendientes en descenso.** En el descenso de toda pendiente se observará siempre una reducción en lo que hace al consumo de combustible, sobre la cantidad requerida generalmente en una vía á nivel; asi como en el costo de salarios por haber recorrido una distancia dada en menos tiempo; pero el descenso de pendientes fuertes resulta, sin embargo, incómodo y costoso, por el desgaste de frenos y ruedas.

**37. Efecto de la longitud de la pendiente sobre la fuerza de tracción.** En una subida larga, a menos que se reduzca la velocidad, el *exceso* de presión con que la caldera haya entrado en la pendiente, se emplea y puede agotarse a cierta distancia según la carga y la inclinación de la pendiente. Así, la fuerza de tracción está limitada por las propiedades generadoras de la caldera; y debe contarse con que la fuerza media de tracción, en toda la pendiente disminuirá a medida que aumente la longitud de la pendiente. Comparando diversos casos, el señor Beverley S. Randolph encuentra, aproximadamente :

| Longitud de una subida continua (kilómetros): | 0 | 8 | 16 | 24 | 32 y más |
|---|---|---|---|---|---|
| Fuerza media de tracción = | 31 | 24 | 19 | 17 | 16 % de peso en las motrices. |

La inclinación parece no afectar estos números considerablemente. Am. Soc. C. E., Trans Vol 70, dic. 1910, p. 323.

**38. Subidas y bajadas.** No obstante lo dicho, las pendientes menores (y aún más fuertes que las reglamentarias) pueden á menudo entrar debidamente en el perfil de un ferrocarril. Su adopción puede ocasionar grandes economías en la construcción, evitando desmontes y rellenos importantes. Para lo concerniente á « pendientes reglamentarias », véase ¶ 11, pag. 1156.

(Véase tambien *N. del T.* al pie de esta pagina).

**39. Pendiente de aceleración** es la pendiente dada con el fin de ayudar a parar o dar impulso a los trenes en una estación situada en la cumbre de la pendiente, o de acelerar o retardar su velocidad en un punto dado. Tales pendientes pueden reducir no solamente el deterioro de las llantas de las ruedas y de las calzas de los frenos sino tambien el esfuerzo necesario para reanudar la velocidad, y además el tiempo que ambas operaciones exigen. Su empleo es frecuente en las líneas de cambios rápidos, aun cuando implique mayores excavaciones para subterráneos, o pronunciadas subidas, para los pasajeros, a estaciones elevadas.

---

(*N. del T. al* ¶ 38. — Además de lo dicho por el autor, suele ser decisivo para hacer pendiente parte de una línea ó su totalidad, cuando se logra con aquellas, como resulta muchas veces, acortar la longitud de la línea. En este caso debe calcularse si el mayor costo de explotacion por kilómetro del trayecto en pendieute multiplicado por sú longitud, es menor que el producto de la mayor longitud de la linea más suave por el menor costo kilométrico de su explotación. Si a esto se agregan los intereses del capital de costo en cada una, se tendrán los mas importantes datos para la elección; pero es muy cierto que hay muchas circunstancias locales que tambien influyen sobre la adopción de una ú otra vía.)

**40. Pendiente de impulsión** se llama asi á la que, aunque muy fuerte, es tan corta que cualquier tren, con velocidad razonable, puede pasarla sin perder demasiada velocidad. Es de ordinario tan fuerte que un tren no podría pasarla sin « cobrar impulso », ó volver a arrancar si está parado en ella.

**41.** Las pendientes de impulsión deben, por consiguiente, adoptarse solamente después de considerar todas las circunstancias probables o posibles que tiendan a parar el tren; tales como cruceros de pendiente, curvaturas, desviaderos, depósitos de agua, estaciones, etc., en, ó cerca de la pendiente; o la posible instalación futura de tales cosas. Si el peligro de las paradas es pequeño; o si un tren, cuando está parado, puede prontamente retroceder, y emprender la marcha otra vez, y si el retardo para el tráfico subsiguiente no es serio; entonces, la pendiente de impulsión está permitida.

**42. Limitaciones de pendientes en subida.** *Arranque en subida.* Cuando los trenes deben arrancar hacia arriba, la pendiente debe ser tal (Webb) que permita una aceleración cuando menos de 24 kilometros por hora en 300 ms. (Alaska Central Ry.)

**43.** En las cortadas, aun donde existen otrasc ircunstancias que permitan el uso de una linea horizontal, es costumbre establecer una pendiente no menor de 2 por mil, con objeto de facilitar los desagües.

**44.** Un *ferrocarril especifica* que, en las vías laterales, ninguna pendiente debe pasar de 5 %, en una tangente, ó de 3 % en una curva, ó de 1 % donde los carros se cargan.

**45. Limitaciones de pendientes en bajada.** La velocidad adquirida al bajar una pendiente, depende en parte de su desnivel y en parte de la proporción de la pendiente. Véase Clasificación de pendientes, pag. 1159, ¶ 37. El declive no deberá nunca ser tal que los trenes de carga (abandonados a su propio impulso) adquieran velocidades que excedan digamos de 48 a 56 km por hora; ni deberá tampoco reducir la velocidad de trenes ascendentes a menos de 16 km por hora.

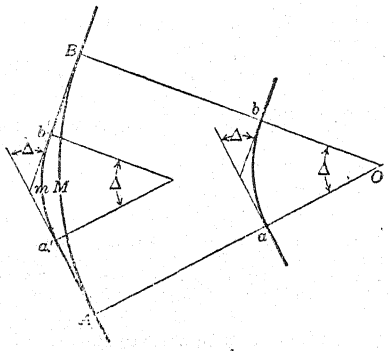

Fig. 4.

**46. Curvas verticales.** Deben emplearse donde quiera que haya un cambio de pendiente marcado. Evitan los choques tanto en el avance como en los retrocesos, debido á que se aflojan ó se aprietan los enganches entres los carros y evitan el peligro consiguiente de que el tren se parta en dos.

**47.** En la fig. 4, considerando la resistencia de la curva como proporcional a la agudeza, $D$, o aproximadamente inversa al radio, $R$ (véase Resistencia de trenes, pag. 1134, ¶ 40), supongamos :

| | Para la curva $A\ M\ B$. | Para la curva $a\ b$ |
|---|---|---|
| $n$ = ..... | $R/r$ | $R/r$ |
| Agudeza = aprox..... | $d = D/n$ | $D = n\ d$ |
| Radio = ..... | $R = n\ r$ | $r = R/n$ |
| Resistencia de la curva = aprox... | $f_c = F_c/n$ | $F_c = n\ f_c$ |
| Longitud de la curva, en cadenas de 100 pies..... | $L = n\ l$ | $l = L/n$ |

Extension o desarrollo o áng del centro... $\Delta = Ld = n\ l\ D/n = l\ D$.

**48. Energía.** Luego, por la energía, $Ec$, gastada (= trabajo hecho) en equilibrar la resistencia de la curva, solamente en cualquiera de estas dos curvas de idéntica abertura, $\Delta$, tenemos :

$$E_c = F_c\ l = n\ f_c\ L/n = f_c\ L.$$

En otros términos, el trabajo debido a la curva es el mismo en ambos casos; y, si en cualquiera de estas curvas fuera acortada o aumentada su amplitud $\Delta$ el trabajo debido a la curvatura variará en proporción.

**49. Trabajo proporcional a la curvatura.** Por consiguiente, suponiendo (como antes) $F_c = n\ f_c$, encontramos que el trabajo, debido tan solo a la curvatura, en *cualquier* curva, es proporcional a, $\Delta$, y es independiente de su agudeza, $D$, o de su radio, $R$.

**50. Pero, comparando las dos líneas,** $A\ M\ B$ y $A\ m\ B$ de la misma $\Delta$ (esta última incluyendo las tangentes, $A\ a'$ y $b'\ B$), tenemos : longitud $A\ m\ B >$ longitud $A\ M\ B$ ; y por consiguiente el trabajo en partes no curvas en $A\ m\ B >$ que en $A\ M\ B$ ; y como hemos visto (¶ 49), el trabajo debido a la curvatura es *igual* en las dos líneas de idéntica $\Delta$, es claro que el trabajo total en $A\ m\ B$ (= trabajo en la parte no curva, en $A\ m\ B$ + trabajo de la parte curv. en $a'\ m\ b'$) > trabajo total en $A\ M\ B$.

## Compensación de las curvas por las pendientes.

**51.** En virtud del aumento de resistencia, debido a las curvas, es costumbre (cuando es posible) reducir las pendientes en las curvas, a fin de que su resistencia total (pendiente + curv.) no exceda a la de la *tangente* con la pendiente original.

**52. El tipo de compensación (tipo de reducción de pendiente)** es la reducción de pendiente por cada grado de agudeza, $D$. De modo que « 0.04 » significa una reducción de pendiente de 0.04 por ciento de pendiente por cada grado de agudeza, $D$ ; así es que, por una curva de 5°, con 0.04 de compensación, en una pendiente de 0.7 por ciento, tendríamos :

Pendiente reducida o compensada :

$$= 0.7\ \% - (0.04 \times 5)\ \%$$
$$= 0.7\ \% - 0.2\ \% = 0.5\ \%.$$

**53. Las pendientes que llegan al límite** (Véase ¶ 11, pag. 1156.) deberán ser siempre compensadas, si es posible; puesto que la pendiente límite, en una *tangente*, ofrece la resistencia máxima que la locomotora normal puede vencer; y cualquier resistencia *adicional* (por ejemplo : la de una curva) tendería a parar los trenes.

**54. Las pendientes que no llegan al límite** (véase p. 1156, ¶ ¶ 12-14) no necesitan ser compensadas más allá de una amplitud en que la pendiente compensada llegue a ser equivalente a la pendiente límite. En muchos casos no se necesitará compensación en las pendientes que no llegan al límite; pero, en toda pendiente no compensada, la existencia de las curvas implica un aumento en el costo, debido unas veces a la reducción de velocidad, otras al aumento del gasto de combustible. La compensación resulta, por tanto, deseable siempre, aun en los casos en que no sea realmente necesaria.

**55.** La compensación, llevada a tal grado que resulte una pendiente en bajada, es desfavorable al tráfico en la dirección contraria, pero esto no implica necesariamente que no deba hacerse. Por ejemplo, el tráfico de regreso puede ser con trenes muy livianos como cuando se trata de carros de carbón o de minerales que regresen vacíos.

**Práctica.**

**56. Proporción.** Algunas autoridades consideran una proporción compensatoria excesiva la de 0.03 por ciento, por grado de agudeza, mientras otras creen que 0.04 es insuficiente. El promedio de éstas, = 0.035, es generalmente aceptado como una justa proporción, con modificaciones, como las anotadas anteriormente, para circunstancias especiales.

**57. Las diferencias entre las diversas vías,** como la estrechez del cartabón, es decir, la falta de juego en la vía, el peralte, etc., entran por mucho en la práctica en esta materia.

**58. Proporción mayor.** Los factores que tienden a aumentar la proporción o tipo de compensación son : la preponderancia de trenes pesados de carga a baja velocidad; la probabilidad de que los trenes tengan que disminuir su velocidad y, si es necesario, hasta detenerse permaneciendo por algún tiempo en la curva; la existencia de un sitio de paradas inmediatamente *antes* de una curva, en cuyo caso se ha recomendado (Webb) una compensación hasta de 0.10 por ciento; humedad probable en túneles, etc.

**59. Proporción menor.** Por el contrario, pueden usarse proporciones menores de compensación donde predominan los trenes de pasajeros a alta velocidad; y cuando hay un sitio normal de paradas inmediatamente *despues* de la curva, caso este, en que la resistencia de curva puede utilizarse, junto con toda la pendiente, para ayudar a detener el tren.

**60. Cambio en la proporción.** Algunas autores sugieren que la proporción o tipo de compensación debe disminuir a medida que aumenta la agudeza; otros sostienen que el tipo de compensación debe ser proporcional a ella.

## Agudeza máxima.

**61. Teóricamente,** la agudeza máxima permitida es la que, a la mayor velocidad permitida, requiere el peralte máximo permitido.

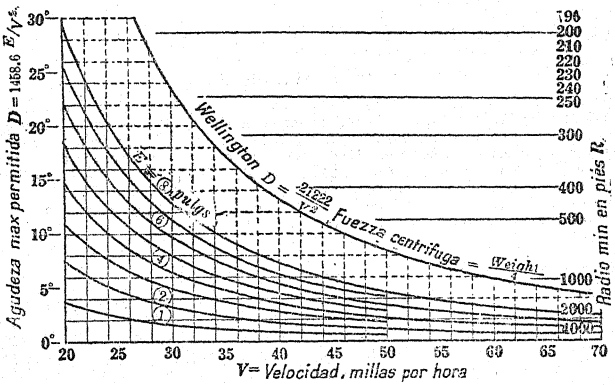

**Fig. 5.**

**62.** En la fig. 5, los ocho diagramas inferiores muestran la agudeza máxim permitida para diferentes velocidades, y para peraltes ó superelevaciones dea

carril exterior desde 1 hasta 8 pulgadas (2,5 á 20 cm en vía normal = 4 pies 8.5 pulg. (1.435 m), conforme a la ecuación 118, Curvas, Superelevación, pag. 1040, ¶ 176; $E$ pulg. = $V^2$ $D$/1458,6, de donde resulta $D$ = 1458,6 $E/V^2$. El diagrama superior indica la agudeza exigida por el señor A. M. Wellington (Trazados de Ferrocarriles, p. 270; Am. Ry Eng. & M. W. Assn., Procs., 1910, vol. II, parte I, p. 681). Fuerza centrífuga $>$ Peso/4.

**63.** Prácticamente, la agudeza máxima se rige también segun las condiciones del terreno y del tráfico. Camp (« Vía », p. 257) indica lo siguiente como práctica corriente en lo que hace al servicio de vía principal y ancho normal de vía.

| $D$. | $R$, piés. | |
|---|---|---|
| $>$ 4° $<$ | 1433 | considerada como aguda; |
| 10° | 574 | — — muy aguda; |
| 15° | 383,1 | límite material para velocidad completa; |
| 20° | 287,9 | usado, como obligatorio, con reducción de velocidad; |
| 22° | 262,0 | — — — — |

Nosotros añadimos :

| | | |
|---|---|---|
| 12° | 478,3 | agudeza máxima normal (con espirales) Alaska Central Ry., 1909; |
| 14° | 410,3 | agudeza máxima normal (con espirales) N. Pacific Ry., 1903. |

Curvas de agudeza hasta de 67° (90 pies (27.45 m) de radio) se han usado en los ferrocarriles elevados de la ciudad de Nueva York.

**64. Para vías secundarias ó derivadas** se hallan en uso las siguientes agudezas :

| $D$. | $R$, piés. | |
|---|---|---|
| 17° | 338 | cuando se trata de grandes locomotoras para colocar vagones en vías derivadas; |
| 29° | 200 | para vagones acoplados de muebles; |
| 39° | 150 | — carboneros acoplados, y para vagones encajonados empujados por locomotoras de transporte de 4 ó de 6 ruedas; |
| 95° | 60 | para vagones tirados por caballos o por locomotoras pequeñas de transporte en vías derivadas de almacenes, etc., con muy bajas velocidades. |

**65. Guarda carriles.** Se usan generalmente en curvas de 16° ($R$ = 359.3 pies = 109,51 m.) y de mayor agudeza.

## Agudeza mínima, etc.

**66.** A veces se especifica que la agudeza *no* deberá ordinariamente, ser *menor de* 1° (para $R$ = 5730 pies) ($R$ = 1746,5 m) excepto cuando el desarrollo ó áng central $\Delta$, $<$ 3°; que la longitud de la curva debe ser $\not<$ 300 pies (como 90 m); y que una **tangente**, $\not<$ 500 pies (150 m) de largo, deberá usarse entre dos curvas en la *misma* dirección, y una tangente, $\not<$ 600 pies (como 180 m) de largo; entre dos curvas en direcciones opuestas.

Véase asímismo Guardacarriles, ¶ 65; Ancho de vía en las curvas, pag 886; Superelevación o peralte, pag. 1039, etc.

# COSTO DE EXPLOTACIÓN

## GENERALIDADES

**1. El proyecto** y la construcción de un ferrocarril y de su material rodante (como su rendimiento) dependen grandemente (1) de la cantidad y la índole del tráfico que se espera tener, (2) de los ingresos resultantes, (3) de los fondos disponibles para construcción, y (4) de los gastos (gastos fijos más el costo de explotación). Las primeras tres partidas las calculan generalmente los promotores; pero el cálculo de la construcción y funcionamiento son las más de las veces de la incumbencia del ingeniero.

**2. Los costos de construcción y de explotación**, dependen principalmente de :

(1) La topografía del terreno;

(2) Las facilidades para disponer de las necesarias cantidades de material y mano de obra;

(3) El carácter y la importancia del tráfico posible;

(4) El carácter y la importancia del material rodante propuesto (fuerza motriz y vagones);

(5) La cantidad de dinero disponible para construcciones.

**3. El problema.** Informado de todo lo que concierne a estos puntos, el ingeniero se ocupa particularmente de hacer lo mas adecuada posible a la topografía del terreno, la línea que mejor responda a las necesidades, teniendo como finalidad (desde el punto de vista de los interesados) el rendimiento o ganancia que produzca el dinero invertido.

**4. La comparación entre dos líneas en proyecto**, *A* y *B*, puede basarse (1) en sus costos respectivos de construcción, más los valores capitalizados de sus respectivos costos de explotación; o (2) en sus respectivos costos de explotación, más la valorización anual de sus respectivos costos de construcción. Podemos, pues, suponer un caso donde los costos por milla de las dos líneas, *A* y *B*, se comparen así : (capitalización al 6 %).

| | (1) Capitalizado. | | (2) Anual. | |
|---|---|---|---|---|
| | *A*, $. | *B*, $. | *A*, $. | *B*, $. |
| Construcción..... | 25,000 | 20,000 | 1,500 | 1,200 |
| Explotación ..... | 100,000 | 125,000 | 6,000 | 7,500 |
| Total..... | 125,000 | 145,000 | 7,500 | 8,700 |

En este caso, para un rédito dado, la línea *A* es preferible, no obstante su mayor costo de construcción. Para Presupuestos sobre el costo de construcción ferroviaria, véase pág. 1166.

## MILLA DE TREN, Y COSTO POR MILLA DE TREN

**5. La milla de tren, « m — t ».** Cuando un tren de cualquier longitud, peso o carácter) recorre (en cualesquiera condiciones) una milla se llama a eso : una milla de tren y se indica así : $(m - t)$.

**6. Costo, m, de la milla de tren.** Por cualquier serie dada de operaciones (como en las operaciones de cualquier línea en un día, o en todas las operaciones de una región en un año) el **costo medio de m — t** es :

$$m = \frac{\text{costo total de las operaciones}}{\text{número de millas de tren recorridas}}$$

De modo semejante, el costo de $m - t$, debido a cualquier partida o partidas dadas de operaciones (exploitación), es :

$$\frac{\text{Costo de operaciones debidas a dicha partida o partidas.}}{\text{Número de } (m - t) \text{ recorridas}}$$

**7. Costo medio de « m − t » en los EE. UU.** En el 24º informe anual de la Comisión de Comercio Interior (véase Tabla 1, a continuación), encontramos como promedio total del costo de « $m - t$ », para las tres clases de líneas consideradas, el año de 1911 :

| Clases. | Costo anual de explotación en bruto. | $E$ = total costo anual de explotación. (Declaración 41). | $T$ = total recorrido anual en millas de tren. (Declaración 36, p. 49.) | $m = E/T = (m - t)$ costo. |
|---|---|---|---|---|
| I..... < | $1,000,000 | $1,844,065,958 | 1,185,632,129 | $1.555 |
| II..... < | $1,000,000 | $ 57,092,361 | 42,315,853 | $1.349 |
| II..... > | $ 100,000 | | | |
| III..... > | $ 100,000 | $ 13,472,094 | 9,552,156 | $1.410 |
| Totales y promedio.. | | $1,914,630,413 | 1,237,500,138 | $1.547 |

Los informes de I. C. C. relativos a 1890-9 dan valores de $m$ que fluctúan solamente entre $0,918 y $0,984; promedio, $0,952.

En nuestras discusiones subsecuentes, suponemos $m$ = $1,50.

**8. Salida.** — El costo $m$ de milla de tren ($m - t$), varía considerablemente, no tan solo (de un tiempo a otro) con la fluctuación de la unidad de costo sino (en un tiempo dado) entre líneas diferentes. Véase ¶ 7. No obstante, dado el costo por unidad, el costo de $m - t$, en una línea determinada, es prácticamente constante, porque el trabajo requerido para mover un tren sobre la línea es fijo dentro de límites reducidos, por el hecho de que la economía prohibe el uso de una carga menor del máximum, y esto a su vez está determinado por las condiciones de la línea. Véase ¶ 10.

## Distribución del costo por milla de tren.

**9. Tabla 1.** Esta tabla contiene los percentajes del costo de $m - t$, atribuidos a las diferentes partidas que forman ese costo, según lo determinó la Comisión de Comercio Interior. Los presupuestos o cálculos de estos tantos por cientos varían mucho; pero los tantos por cientos contenidos en la tabla 1 representan el promedio de la práctica americana, constituyendo así una guía útil subordinada a modificaciones en los casos en que las condiciones especiales obligan a desviarse de las condiciones normales.

Costo de explotación.
Tabla 1.

Sacada del Informe anual vigésimo cuarto de la Comisión de Comercio Interior (para el año que termina en 30 de Junio de 1911) de la Estadística de Ferrocarriles en los Estados Unidos, publicada por la Imprenta del Gobierno, en Washington, 1913.

| Ferrocarriles de..... | Clase I*. | Clase II*. | Clase III*. |
|---|---|---|---|
| Millas de línea..... | 215,146 | 19,120 | 9,167 |
| Millas de vía..... | 328,800 | 22,989 | 11,036 |

Análisis de los gastos de explotación.

## COMPARACIÓN DE LÍNEAS

### Factores determinantes y no determinantes.

**10.** Al comparar líneas alternativas, los factores por considerar, que afectan principalmente los costos de manipulación: son *diferencias de pendiente*, de *curvatura* y de *longitud*. Considerados colectivamente y con relación a su efecto sobre el costo de explotación, las pendientes y las curvas se dividen en dos clases generales, que es menester distinguir con cuidado, a saber: curvas y pendientes compensadas y no compensadas, o reglamentarias y no reglamentarias, o « mayores » y « menores ».

**11. La curva o pendiente compensada ó reglamentaria** o la combinación compensada de pendiente y curvatura, en una sección de locomotoras dada, es la que afecta el costo de manipulación *limitando la longitud y el peso del tren* que, en condiciones normales de trabajo y sin « impulsión », puede una locomotora transportar a través de la sección; y de ese modo, limita el número mínimo de trenes (e igualmente el trabajo mínimo) necesario para un tráfico dado.

**12. Trabajo total.** Con una fuerza motriz dada, *el peso máximo de un tren*, que puede ser transportado en una línea dada (aunque prácticamente independiente de la longitud de la línea), se ve así determinado por condiciones limitadas de pendiente o de curvatura o por entrambas combinadas; pero el trabajo total requerido, para transportar este peso máximo de tren por la línea, puede ser afectado por no limitar las condiciones en cuanto a longitud, como lo fué por causas de pendientes o curvaturas.

**13. Por consiguiente**, supongamos que, con una locomotora dada, una curva larga de 12° (inevitable en cada una de las dos líneas alternativas, *A* y *B*) hace que sea 500 ton. el peso máximo de un tren que puede ser transportado en cualquiera de las dos líneas. Esa curva constituye por tanto un factor limitador ó « mayor ». Pero, si la línea *B* tiene también una o más curvas de 4°, o pendientes cortas, que no existen en la línea *A*, o si la línea *B* es más larga que la línea *A* (siendo las dos líneas por lo demás, semejantes), entonces la línea *B* requiere mayor trabajo que la línea *A* para arrastrar el expresado tren de 500 ton. sobre la vía; y este exceso de esfuerzo contribuye a hacer más costosa la explotación de la línea *B*.

**14.** En consecuencia tenemos:

| | Que afectan. | Que no afectan. |
|---|---|---|
| Pendientes y curvas: | | |
| Que limitan..... | peso máx. del tren. | trab. del tren máx. |
| Que no limitan..... | trab. del tren máx. | peso máx. del tren. |
| Diferencias de longitud..... | — | — |
| Pendientes de empuje..... | — | — |

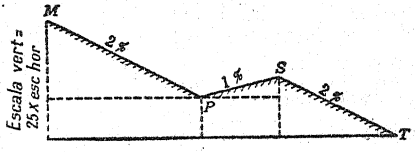

**Fig. 1.**

**15. Pendientes muy fuertes. Pendiente de limite.** El límite de la pendiente no es necesariamente la más fuerte de la sección. Así:

(1) Una pendiente corta, más fuerte que la pendiente ordinaria puede ser pasada por los trenes y locomotoras reglamentarios, mediante una « impulsión ». (Véase ¶ 40, pag. 1149.)

(2) Fig. 1. Cuando hay, por ejemplo, vagones cargados que se mueven de *M* a *T*, regresando vacíos de *T* a *M*, la pendiente *más ligera y más corta*, *P S*, contraria al *tráfico más pesado*, puede ser la pendiente ordinaria o de límite.

(3) El límite puede ser una combinación de pendiente moderada con curvatura fuerte.

**16. Límite de agudeza.** De modo semejante, la curva de límite, de una sección, puede ser larga y relativamente suave. Además, el efecto limitativo de una curva dada puede ser eliminado por la reducción de la pendiente. Véase pag. 1150 ¶ 51, etc.

Para el análisis del efecto de las pendientes y curvas límites, sobre el costo de explotación, véase ¶¶ 19 a 24.

**17. No son factores de limitación** :

(1) Las diferencias de longitud;
(2) Las pendientes de empuje;
(3) Curvas..... } no limitadoras.
Pendientes..... }

## Cálculos.

### Métodos de Procedimiento.

**18.** Cuando se trata de comparar los costos de explotación de dos líneas, afectadas por diferencias limitantes o no limitantes de pendientes, de curvatura y de longitud, se calcula (compárese Tabla 2) :

1. El costo normal por milla de tren ($m - t$) de cada operación;
2. El tanto por ciento, $a$, con que cada uno de estos costos parciales contribuye a formar el costo total de $m - t$, $m$ (véase Tablas 1 y 2);
3. El grado (tanto por ciento, $b$, de $a$) en que el costo de cada partida se halla afectada por la diferencia de pendiente, la diferencia de curvatura o la diferencia de longitud en cuestión;
4. El cambio consiguiente ($a' = b\,a$, percentaje de $m$) en el valor $a$, del tanto por ciento de cada partida, debido a la diferencia en cuestión;
5. La suma, $A'$, de los valores de $a'$, obtenidos en el término « 4 »; es decir, el costo total de $m - t$ de la diferencia en cuestión, expresado como un tanto por ciento del costo $m$ total y normal de $m - t$;
6. $m' = A'm$ = al costo de $m - t$ de la diferencia en cuestión, expresado en dólares;
7. $C_t$ = al costo anual de la diferencia en cuestión; ¶ 43.
8. $V_c$ = al valor capitalizado de la diferencia en cuestión.

### Ejemplo del Método.

Construcción de la primera columna (« Tren adicnl. ») de la Tabla 2.

**Factores limitadores.**

**19. Ejemplo.** — Por el concepto de Mant. de Vías y Estructuras, supongamos :

$t$ = número normal de viajes redondos diarios;
$m_s$ = costo $m - t$ supl de viajes normales, $t$;
$a_s = 100\ m_s/m = m_s$ como percentaje de $m$;
$S$ = costo supl normal, total y diario;
$t'$ = número de viajes redondos diarios adicionales;
$m_s'$ = costo $m - t$ supl de viajes adicionales, $t'$;
$a_s' = 100\ m_s'/m = m_s'$ como percentaje de $m$;
$s$ = aumento en $S$, debido al tren adicional;
$L$ = longitud de la línea, en millas.

Vamos a suponer que, con un alineamiento y un perfil dados, 10 viajes redondos al día ($t = 10$) se necesiten para manipular un tráfico dado, y que un aumento de pendiente o curvatura, o ambos, debido a algún cambio propuesto en la línea, redujera el peso máximo del tren a tal grado que se requieran 11, en vez de 10, viajes redondos para el mismo tráfico.

Entonces :

$$t' = 11 - 10 = 1; \quad \text{y} \quad t'/t = {}^1/_{10}.$$

**20. Para encontrar b.** Supongamos que este aumento de $^1/_{10}$, en $t$, aumenta el costo total de administración, $S$ (primera partida de la Tabla 2) en $^1/_{100}$ o **1 %** solamente.

Entonces :

$$\frac{s}{S} = \frac{L}{L}\,\frac{t'}{t}\,\frac{m_s'}{m_s} = \frac{t'}{t} \times \frac{m_s'}{m_s} = \frac{1}{100}\text{; y (¶ 18,4) :}$$

$$b_s = \frac{a_s'}{a_s} = \frac{m_s'}{m_s} = \frac{s}{S} \times \frac{t}{t'} = \frac{1}{100} \times \frac{10}{1} = \frac{1}{10} = 10\ \%;$$

o, en este ejemplo, el costo $m - t$, $m_s'$, de suplemento, por el tren adicional, es **10 %** del costo suplementario normal, $m_s$.

**21. Efecto sobre los demás elementos del costo.** Entonces, calculando un promedio de los valores de $a$ para las tres clases de vía en Tabla 1, ¶ 9, usando números redondos para mayor facilidad, y aplicando percentajes supuestos, $b$ (sujetos, por supuesto, a amplias variaciones en diferentes circunstancias), a los elementos restantes del costo de manipulación, obtenemos (tan solo a manera de ilustración del método) los demás valores de $a'$ ($= b\ a$) indicados bajo el rubro de « tren adicional » en la Tabla 2.

**22. Sumando** estos valores de $a'$, obtenemos $A'$, = 43.8, como el costo $m - t$ del tren adicional, expresado como tanto por ciento del costo $m - t$ normal, $m$. Entonces :

$$m' = A'\ m,$$

donde $m$ = al costo $m - t$ normal total, considerado aquí en $1.50.

**23.** En este caso, por consiguiente, tenemos, como costo $m - t$ del tren adicional requerido por los factores determinantes :

$$m' = A'\ m = 0.438 \times \$1.50 = \$0.657.$$

**24.** A, $m'$, así encontrado, deberá añadirse una pequeña suma (digamos de 1 a 1.5 centavos) para cubrir los intereses sobre el costo de cada locomotora y ténder adicionales requeridos.

**Otros factores (no determinantes).**

**25.** En sus columnas restantes, la Tabla 2 ofrece análisis semejantes en relación con los demás factores del costo de manipulación (no determinantes) : a saber, — longitud, pendientes de empuje, altos y bajos, y curvatura. Véase abajo.

**26. Diferencia de longitud.** Con un peso máximo dado de tren (determinado por la pendiente limitativa, por la curvatura, o por ambas), un aumento de longitud aumenta el costo de manipulación, ocasionando un trabajo adicional en cada tren, a saber : el trabajo de transportar el peso máximo del tren sobre la longitud adicional.

**27.** *Diferencias de longitud grandes y pequeñas.* En cualquier diferencia de longitud (grande o pequeña), el costo de vía y mantenimiento por $m - t$ equivaldrá aproximadamente al costo normal de esas partidas; pero el costo de salarios de trenes por $m - t$ (que, en una gran diferencia de longitud, puede igualmente equivaler al costo normal), son despreciables en diferencias de longitud pequeñas. El efecto de estosobre el presupuesto puede ser ilustrado con un caso, asi : se acepta (para mayor facilidad) que la vía y el mantenimiento de vía asciendan normalmente a 15 %, y los jornales de trenes a 13 % (compárese Tabla 1) del costo total de manipulación, suponemos los valores probables de $b$, encontramos los valores consiguientes de $a'$ y comparamos así los efectos de las diferencias de longitud grandes y pequeñas por lo que se refiere a la suma de los costos de estos dos elementos únicamente.

| | Normal en toda la línea. | En gran dif de long. | | En pequeña dif de long. | |
|---|---|---|---|---|---|
| | $a$ % de $m$. | $b$ % de $a$. | $a'$ % de $m$. | $b$ % de $a$. | $a'$ % de $m$. |
| Mant. de vías y caminos.... | 15 | 100 | 15 | 100 | 15 |
| Jornales de trenes..... | 13 | 100 | 13 | 0 | 0 |
| % $m$, del costo total $m - t$, por estos dos elementos únicamente..... | 28 | | 28 | | 15 |

**28.** Las diferencias de longitud se clasifican a veces como sigue :

| | Diferencia de longitud. Clases. | | |
|---|---|---|---|
| | *A.* | *B.* | *C.* |
| Jornales de trenes..... | *No afectado.* | **Afectado.** | **Afectado.** |
| Número de estaciones o andenes..... | *No afectado.* | *No afectado.* | **Afectado.** |

Los efectos de las diferencias de longitud sobre el costo de manipulación se hallan indicadas en la Tabla 2.

**29.** *Efecto de la diferencia de longitud sobre los ingresos.* De dos vías de competencia, entre dos puntos dados, cualquiera de ellas perderá fletes si cobra más caro que la otra. Por consiguiente, en los casos de competencia, las tarifas, en ambas líneas, entre dos puntos dados, son generalmente (en igualdad de otras circunstancias) las propias a la línea más corta, y esta es una ventaja importante; puesto que la línea más corta es la de más bajo costo de manipulación.

**30.** Pero, no habiendo competencia, las tarifas de carga y pasajeros se basan de ordinario en la distancia recorrida; y el producto de una línea, entre dos puntos dados, es en consecuencia absolutamente proporcional a la longitud de la línea; mientras que el costo total de manipulación en general aumenta con menos rapidez que el de la longitud de la línea. Por tanto, no existiendo competencia, la línea más larga es en general la más remunerativa.

**31. Es pendiente de empuje** la que, por ser tan inclinada, y tan larga, necesita regularmente dos o tres locomotoras (en vez de una) en cada tren que la sube. Por consiguiente, cuando las locomotoras de empuje son de igual potencia que las locomotoras ordinarias, la pendiente de empuje se hace generalmente dos o cerca de tres veces más inclinada que la pendiente límite en la sección, según que cada tren requiera dos locomotoras o tres.

**32.** En teoría, por consiguiente, la primera locomotora proporciona, al igual de cada una de las de empuje, tan solo la potencia necesaria para transportar el tren máximo por la pendiente ordinaria de límite; y el trabajo de cada equipo de empuje, es teóricamente solo el necesario para arrastrar o transportar el tren máximo en un *trecho adicional* (= longitud de pendiente de empuje) de la pendiente ordinaria de límite.

Para el análisis del costo de explotación en pendientes de empuje, véase Tabla 2.

**33.** Véase Tabla 2. *Las pendientes de empuje* afectan principalmente las partidas de :

Mantenimiento de Vías y Caminos.
Reparaciones y renovación de locomotoras, carros, etc.
Combustible y gastos de locomotoras.

**34.** El costo total anual de explotación, de una *locomotora de empuje y su tênder* varía ordinariamente entre $7,500 y $18,000, con $10,000 a $15,000 como límites más probables.

**35. La pendiente menor o no limitada,** es menos inclinada que la pendiente de límite (¶ 11), o tan corta que puede ser subida, por « impulso adquirido » (pag. 1156, ¶ 40), por una locomotora normal que arrastre el tren máximo. Afecta, pues, el costo de explotación porque exige un esfuerzo adicional para arrastrar el tren máximo. Los problemas relacionados con las pendientse que no son de límite se llaman generalmente problemas de « **subidas y bajadas**».

Comparando las definiciones de $s_e$, $h_t$, $h_e$ y $L_s$, ¶¶ 39 y 43, se verá que el esfuerzo adicional, ocasionado por una pendiente menor, se iguala con el de transportar el tren máximo en un *trecho adicional* de vía a nivel, cuya extensión es tal que el trabajo de este transporte, en ella, es igual al de levantar el peso del tren a la altura vertical de la pendiente.

Para el análisis de problemas relativos a pendientes que no son de límite véase ¶ 39).

**36. De modo semejante,** una curva menor que no es límite es a veces menos aguda que la curva límite, y otras tan corta que una locomotora ordinaria puede atravesarla con el tren máximo. Afecta el costo de explotación, aumentando la resistencia que la locomotora, que arrastra el tren máximo, debe vencer. Aumenta así el trabajo necesario para mover el tren máximo en la línea.

Comparando las definiciones de $D_e$, $\Delta d$, $\Delta_e$ y $L_c$, ¶¶ 39 y 43, se verá que el esfuerzo adicional, ocasionado por una curva, se iguala con el de transportar el tren máximo sobre el *trecho adicional* de la vía recta, cuya longitud es tal que el trabajo de ese transporte, en ella, es igual al que resulta de la curva.

Para análisis de problemas relacionados con curvas menores, más suaves, véase ¶ 39.

**37. Clasificación de pendientes que no son límites,** fig. 2, pág. 1163. De acuerdo con la marcha de los trenes de descenso, las pendientes que no son límites se hallan clasificadas como en la tabla de la pág. 1160, ilustrada por la fig. 2, pág. 1163. Compárese J.-B. Berry, Am. Ry Eng. M. W. Assn., Boletín 49, marzo 1904, pag. 21; y A. M. Wellington. Trazado de vías, págs 330 y 374, y Tabla 122, págs 372-3.

| | Clase de pend. Véase fig. 2, pág. 1163. | | |
|---|---|---|---|
| | *A.* | *B.* | *C.* |
| Caída (altura de).. | > 30 pies (9,15 m). | > 30 pies (9,15 m); pero > caída indicada para una curva sólida. | > caída indicada para una curva sólida. |
| Observaciones..... | Efecto desprec. | No sobrepujará locom. de subida. | Las locom. de subida deben usar arena. |

De ordinario una velocidad inicial de 10 mill/h no alcanzará 30 mill/h si :

| | *A* | *B.* | *C.* |
|---|---|---|---|
| El vapor está..... | Abierto. | Cortado. | Cortado. |
| Los frenos están... | Sueltos. | Sueltos. | Aplicados. |

**38.** En una pendiente de 0.6 %, el efecto de gravedad longitudinal iguala poco más o menos a la resistencia a 32 mill/h. Por consiguiente, sin vapor y sin frenos, esa velocidad no excederá ordinariamente, en pendientes de esta especie ni en pendientes más ligeras, por larga que sea la pendiente o por grande que sea la altura de caída.

**39. Efecto de las pendientes y curvas no límites sobre el costo de explotación.**

Supongamos :

| | |
|---|---|
| $s_e$ = la pendiente, en pies por 100 pies*. | $D_e$ = la agudeza de curva, en grados de desarrollo por cadena de 100 pies, ¶§. |

que produzcan una resistencia adicional, debida a :

| | |
|---|---|
| pendiente tan solo. | curvatura tan solo. |

igual a la resist. normal, $f_n$ (véase pag. 1129) en una tangente a nivel.

Entonces, para el *trabajo* hecho en un tren dado, al equilibrar esta resistencia adicional solamente, tenemos :

| | |
|---|---|
| En una milla (5.280 pies) de pend. $s_e$, trabajo = levantar el tren 52.8 $s_e$ pies, en cualquier pendiente; * | En una milla (5.280 pies de curva $D_e°$, trabajo = al necesario para equilibrar la resist. de una curva de cualquier agudeza § en 52.8 $D_e°$ de desarrollo. |

i esto es igual también al trabajo para equilibrar la resistencia normal, $f_n$, en una milla de tangente a nivel. Pero el costo del trabajo, necesario para :

| | |
|---|---|
| la elevación de un tren 52.8 $s°$ pies. | para equilibrar la resistencia solamente de una curva, en 52.8 $D_e°$ de desarrollo. |

es mucho *menor* que el *costo* normal, $m$ (digamos § 1.50; véase ¶ 7) de una milla de tren en una tangente a nivel; porque (continúa en la pag. 1161).

* $s_e$ es comunmente 0.5 % = 26.4 pies por milla; o 52.8 $s_e$ = 26.4 pies elevación.

† En vez de 60 % y 65 %, Mr. Berry (*Am. Ry Eng. y M. W. Sssn, Boletín* 49, marzo 1904, pag. 22) toma 25 % y 45 % respectivamente. La diferencia nos indica como cambian tan ampliamente estas apreciaciones según el criterio de cada cual.

¶ $D°$ se toma generalmente por 10°; o bien 52.8 $D°$ = 528° de desarrollo.

§ Pongamos $f_1$ = resist. debida a la curva en una curva de 1°.
Entonces $D_e = f_n/f_1$.
$f_n$ se supone generalmente que varía entre 5 y 10 lbs. y $f_1$ de 0.5 1.5 lb., por ton. de 2.000 libras.

(1) el *gasto* de energía, en el trabajo de subida de los trenes, es a menudo compensado (al menos parcialmente) por una *ganancia* de energía en el *descenso* correspondiente; y :

(2) el costo normal por milla de tren, $m$, incluye elementos que no se hallan directamente afectados por la subida o por la curvatura. Así :

Excepto por la partida relativa a combust., el efecto de subida del tren sobre el costo de explotación es materialmente despreciable. Del costo total por combust. para locom. (= digamos a 10 % del costo normal m-t, $m$, véase Tabla 1), una considerable proporción; un promedio digamos de 45 %, es debida a pérdidas en el fuego, en detenerse, en parar y arrancar y en vencer la resistencia de curvas o pendientes, dejando solamente 55 % como costo de transporte o arrastre en una tangente a nivel, cuyo trabajo en una milla, es igual al necesario para 52.8 $s_p$ pies de subida. A este 55 % el Prof. Webb agrega, en las clases. *B* y *C* (véase ¶ 37) 5 % por combustible en las pendientes de bajada; y en la clase *C*, otro 5 % por pérdidas por los frenos; haciendo un total medio, $b = 60$ % para la clase B, y $b = 65$ % para la clase *C* *. Las pendientes en la clase A son despreciadas, pues no afectan de un modo material el costo de explotación.

Tenemos, por tanto, para todos los componentes (haciendo suposiciones generales por los gastos que no se refieran a combustible de locom. (Véase Tabla 2.)

| Clase B. | $a$. | $b$. | $a$. |
|---|---|---|---|
| Combust..... | 11 | 60 | 6.6 |
| Varios..... | 8 | .. | 2.0 |
| Por pendientes... | $A'$ | = | 7.6 |

$m' = A'\,m$ ;
$= 0.076 \times \$1.50$;
$= \$0.114$.

| Clase C. | $a$. | $b$. | $a'$. |
|---|---|---|---|
| Combust..... | 11 | 65 | 7.1 |
| Varios..... | 8 | .. | 2.0 |
| Por pendientes... | $A'$ | = | 9.1 |

$m' = A'\,m$;
$= 0.091 \times \$1.50$;
$= \$0.136$.

La curvatura afecta principalmente los componentes de mantenimiento de vías y caminos, las reparaciones de locom. y vagones, y el combustible para locom.

Supongamos (véase Tabla 2) :

| | $a$. | $b$. | $a'$. |
|---|---|---|---|
| Mant. de v. y caminos..... | 16 | 75 | 12 |
| Reparaciones : | | | |
| Locom..... | 7 | 100 | 7 |
| Vagones..... | 8 | 100 | 8 |
| Combustible loco.. | 11 | 50 | 5.5 |
| Varios..... | 8 | 25 | 2 |
| Curvatura.... | $A'$ | = | 34.5 |

Por consiguiente, para curvatura :

$m' = A'\,m$.
$= 0.345 \times \$1.50 = \$0.5175$.

Por suplemento de caminos y vías, Mr. J. B. Berry, Am. Ry Eng. y M. W. Assn., Boletín 49, marzo 1904, pag. 20, da (en vez de nuestro $a = 16$ %) $a = 14.76$ %, obtenido como sigue :

| | $a$. | $b$. | $a'$. |
|---|---|---|---|
| Carriles..... | 2.28 | 300 | 6.84 |
| Traviesas..... | 3.01 | 50 | 1.50 |
| Balasto..... | 0.28 | 50 | 0.14 |
| Clavos, etc., etc.. | 0.86 | 100 | 0.86 |
| Varios..... | 8.33 | 50 | 4.16 |
| Supt..... | 14.76 | 91 | 13.50 |

* Véase † nota, pág. 1.160.

| Con $m = \$1.50$, tenemos $m' = A' m =$ ..... | | \$0.657 | | \$0.460 | | \$0.606 | | \$0.828 | |

**40.** La tabla 2 supone valores para $a$ (% de $m$), y para $b$ (% de $a$), y deduce valores de $a$ ($= b\ a$), $A'$ (suma de $a'$) y $m'$ ($= A'\ m$).

**41.** La tabla 2 ilustra la aplicación del método del ¶ 18, para encontrar el costo $m'$ de m-t modificado, debido a cada uno de los diversos factores que afectan el costo de operación, así :

1. Pendientes y curvas limites (tren adicional).
2. Diferencias de longitud.
3. Pendientes de impulsión.
4. { Pendientes no limitadas (subida y caída).
   { Curvas no limitadas.

**42. Advertencia.** Los valores de $b$ (% de $a$) dados aquí, representan simples valores probables, y se usan para ilustrar el método del ¶ 18, mas que para representar verdaderos percentajes. Los verdaderos valores de $b$ varian ampliamente con diferentes condiciones, tambien con la clasificación del costo, y con el criterio del que hace la apreciación. Véase Nota † al pie de la pag. 1160. Debe se restimado en cada caso.

---

* Para trenes adicionales (1.ª columna) J. B. Berry Am Ry Engs M. W. Assn, Boletín 49, marzo 1904, pag. 12, encuentra $A' = 43.29$ % de $m$.

† Usando otra clasificación para las diferencias de longitud J. B. Berry. U. P. Ry A. R. E. M. W. A. Boletín 49, marzo 1904 y E. H. Mc Henry. N. P. Ry 1903, adoptan los siguientes valores de $A'$ :

| | | Clase A. | Clase B. | Clase C. |
|---|---|---|---|---|
| Berry U. Pac..... | $A' =$ | 32 % | 46 % | 59 % |
| Mc Henry N. Pac..... | $A' =$ | 22 % | 52 % | 100 % |

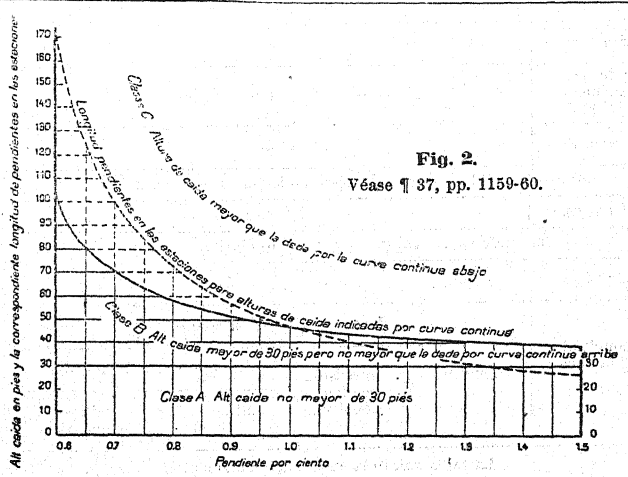

**Fig. 2.**

Véase ¶ 37, pp. 1159-60.

* Cubre todos los capítulos, excepto el combustible para Loco.

**43. Deducción del costo anual y su capitalización.** Teniendo, de acuerdo con los ¶ ¶ 18 a 42, el costo modificado $m'$ de la milla de tren $(m - t)$; determinado por un factor dado en un caso dado; se procede, como se indica a continuación para deducir de $m'$, el costo anual $C_a$, de una diferencia dada (en condiciones limitadas ó no) entre dos lineas, y el valor capitalizado $V_c$, de dicho costo anual.

En el inventario que sigue un « aumento » y sus efectos pueden ser negativos.

Sea.

| | |
|---|---|
| $s_e$ = la pendiente en pies por 100 pies (tanto por ciento), | $D_e$ = la agudeza en grados de desarrollo por cadena de 100 pies, |

que produce una resistencia adicional, a la resistencia normal, $f_n$, en una tangente a nivel;

| | |
|---|---|
| $h_d$ = dif en cuanto a, altura de caida entre dos lineas;<br>$h_e = 52.8\ s_e$<br>= 1 « equivalente a pendiente por milla »<br>= la altura para la cual el trabajo requerido es : | $\Delta_d$ = dif de desarrollo angular entre dos lineas;<br>$\Delta_e = 52.8\ D_e$<br>= 1 « equivalente a una milla en curva »<br>= desarrollo ang en el cual el trabajo debido a la curva es : |

equivalente a la fuerza de arrastre del tren en una milla de tangente a nivel.

Entonces :

| | |
|---|---|
| $L_s = \frac{h_d}{h_e}$ = la dif en cuanto a altura y caida, entre las dos lineas expresado en términos del « equivalente a pendiente por milla », $h_e$. | $L_c = \frac{\Delta_d}{\Delta_e}$ = dif en cuanto a desarrollo angular entre las dos lineas expresado en términos del «equivalente a una milla en curva », $\Delta_e$. |

$C_a$ = costo anual de una dif dada entre dos lineas;
$V_c$ = valor capitalizado de $C_a$;
$d$ = el número (generalmente 365 ó 313) de dias de tren en un año.

| (1). | (2). | (3). | (4). | (5). |
|---|---|---|---|---|
| Sea $t'$ = | $t$ = | | | |
| Nº de viajes adicionales ¶ 11. | Número de viajes redondos por dia. | | | |
| Entonces $d\ t'$ = | $d\ t$ = | | | |

número de millas de tren sobre cualquier milla en un año por :

| | |
|---|---|
| $t'$ trenes, | $t$ trenes, |

haciendo cada uno un viaje redondo diario.

| Sea $L$ = | $L_d$ = | $L_p$ = | $L_s$ = | $L_c$ = |
|---|---|---|---|---|
| longitud de la linea. | dif entre dos lineas en cuanto a : | | | |
| | longitud | impulsión pendiente longitud. | número equivalente de | |
| | | | millas pendientes. | millas en curva. |

(La tabla continúa en la página siguiente.)

(Continuación de la tabla de la página anterior.)

| (1). | (2). | (3). | (4). | (5). |
|---|---|---|---|---|
| **Entonces para un tráfico dado, un aumento en :** | | | | |
| el límite pendientes curvas. | longit linea. | impulsión pendiente longitud. | No limitadas : | |
| | | | Pendientes. | Curvaturas. |
| aumenta el costo de operaciones por : | | | | |
| aumento $t'$ al nº de viajes redondos por dia en $L$; | haciendo que cada uno de los $t$ trenes corra $L_t$ millas, mas en cada viaje sencillo; | requiriendo impulsión del tren en cada viaje sencillo en $L_p$; * | aumentando la resisten en las | |
| | | | pendientes; | curvas; |
| aumentando asi, el trabajo normal con un trabajo equivalente al requerido para arrastrar, diariamente : | | | | |
| $t'$, trenes. | $t$, trenes. | | | |
| sobre una distancia igual a : | | | | |
| $L$. | $L_d$. | $L_p$ *. | $L_s$. | $L_c$. |
| **$m' = A' m$ = costo de la milla-tren de este trabajo adicional.** | | | | |
| **Número de millas trenes equivalentes, adicionales por año** debido a las dif entre las dos lineas = | | | | |
| $d\,t\,L$. | $d\,t\,L_d$. | $d\,t\,L_p$ *. | $d\,t\,L_s$ †. | $d\,t\,L_c$. |
| $C_a$ = **costo anual adicional** = | | | | |
| $d\,t'\,L\,m'$. | $d\,t\,L_d\,m'$. | $d\,t\,L_p\,m'$ *. | $d\,t\,L_s\,m'$ †. | $d\,t\,L_c\,m'$. |
| **$V_c = C_a \div$ la rata de los intereses.** | | | | |

Debe advertirse que, en los cinco casos, el trabajo adicional, es el del arrastre del tren o es igualado al (y establecido en términos del) arrastre. En la columna 1 (diferencias en las condiciones de límites) dicho arrastre es el de los *viajes adicionales* sobre *la misma longitud L*, de linea, en ambos casos; por el contrario, en cada una de las otras cuatro columnas el número de viajes no está afectado por la diferencia entre las dos lineas comparadas y el arrastre es el de dichos viajes (*el mismo* para ambas líneas) sobre una *longitud adicional*, *Ld*, *Lp*, *Ls* o *Lc*, de línea. Véanse ¶ ¶ 32, 35 y 36.

* Esto supone que la impulsion de un equipo en milla, es equivalente a una milla de tren, y que el costo de impulsión del equipo es el mismo en ambas direcciones. Al desviarnos de estas suposiciones, debe dejarse un margen al determinar el valor de *b*, ¶ 18 (8). Véase tambien ¶ 32.

† Esto supone un total igual de altura, en pendientes no limitadas, en ambas direcciones; y desprecia la ventaja de las bajadas por las pendientes.

# PRESUPUESTOS SOBRE EL COSTO DE CONSTRUCCIONES

## PRELIMINARES

### Variaciones y límites.

*N. del T.* — Este capítulo contiene en su mayor parte datos estadísticos que sólo pueden ser útiles a los Ingenieros en trabajos de ferrocarriles en los Estados Unidos, pero, no obstante, hemos extractado todos los datos, informes y observaciones que por ser más generales pueden ser útiles a cualquier ingeniero de este ramo.

Como es natural, al tomar los datos muchas veces salteados, que aparecen entre las págs 1166 a 1179 suelen no tener conexión inmediata, pero siempre son comprensibles y útiles.

En las partes donde hemos salteado algunas líneas ó párrafos ponemos líneas de punto.

**1. Factores que afectan el costo.** El costo de las construcciones ferroviarias en general varía mucho. Depende principalmente de las condiciones topográficas y geológicas de las regiones que la línea atraviese; del valor intrínseco de ellas y del importe de las concesiones o derechos de paso, consiguientes; de la extensión y el precio de los terrenos que se necesiten para patios y estaciones; del de los diversos elementos de construcción; del costo de la mano de obra; de los métodos de construcción que se empleen; de las necesidades generales en cuanto a pendientes y alineamiento de las vías; de la importancia y el carácter del tráfico a que la línea se destine; de que haya o no competencia; de la naturaleza de ésta ; y de los fondos disponibles.

**2. Costo inicial y costo definitivo.** El costo de construcción de un ferrocarril dado, si se basa en los libros de la compañía, aumenta según sea el período de tiempo que la obra requiera; porque el costo original (a menudo mínimo a causa del anhelo económico de poner cuanto antes la vía en condiciones de producir ganancias) puede ser mucho menor que el costo total subsecuente (« Costo original hasta la fecha ») una vez hechas las mejoras deseables. Véanse ¶ ¶ 4 y 11.

**3.** Por otra parte; hay construcciones, incluídas en el costo original, que a menudo son abandonadas; pero que su costo, sin embargo, entra en el costo total de la construcción.

**4. Cuentas.** En cualquier costo efectivo de una construcción dada, las bases del costo son siempre modificadas por la diferencia en el sistema de contabilidad. Por ejemplo, hay partidas que siendo propiamente aplicables a Construcción, con frecuencia se cargan a Mantenimiento de Vías; como cuando se trata de una obra provisional de un caballete de madera (parte de una construcción original) que después se va terminando gradualmente y el servicio de trenes que ella origina se carga a Mantenimiento.

**5.** Al deducir el costo de construcción de una línea en proyecto del de una línea existente, deberá, por supuesto, dejarse un margen por la diferencia de condiciones entre ambas líneas; pues aun tratándose de costos de unidad determinadas, sucede que el costo por milla es a menudo distinto; y por consiguiente :

$$\text{El costo de construcción aparente por milla} = \frac{\text{costo total}}{\text{longitud}}$$

de una parte de la línea en cuestión, puede resultar mucho más costosa, y el de otra parte mucho más baja, que el promedio del costo de toda la línea.

**6. Ejemplo.** Así, una línea principal que corra rumbo al Este desde el Pacífico, atravesando diversos Estados, y que se halle gravada además de un fuerte costo por terrenos en sus estaciones, amén de fuertes gastos de construcción propiamente dicha en la porción de línea que pasa por las montañas, puede pasar también por regiones de más favorable topografía que requieran muy pocos gastos po terrenos. Al usar, por tanto, a manera de comparación, las cifras del costo de construcción de una línea así, deberá tenerse siempre en cuenta la índole particular de la vía que se desea construir. Si, por ejemplo, la línea proyectada pasa por terrenos favorables y de poco costo tan sólo, ni exige terminales costosos, sería descaminado aplicar a ella, sin más modificación, la cifra de costo por construcción referente a toda la línea principal incluyendo sus secciones más costosas.

**7. Tendencia al alza.** Cuando se usen datos primitivos como base para el presupuesto de costos presentes o futuros, téngase en cuenta que la tendencia de todo costo de construcción ferroviaria, considerada en conjunto, es a aumentar; porque la reducción del costo de unidad, en algunos respectos debida a los adelantos de fabricación y a los sistemas de trabajo y perfección de los aparatos, se ve de ordinario más que compensada por el aumento de peso en el material rodante; por la incesante demanda de precisión por parte del público tanto en relación con el tráfico de carga como con el de pasajeros; por el aumento de tráfico, que justifica lo costoso de la construcción en beneficio de la reducción de los gastos de explotación; y por la creciente insistencia de la comunidad para que se eviten las molestias y los accidentes.

**8. De acuerdo con estas ideas,** cuando existen cruces de pendientes, se hace necesario dotarlos con aparatos perfeccionados de señales y de uniones; mas sucede con frecuencia que se necesita suprimir tales crucero en pendientes y la operación puede costar $100,000 o más.

**9.** La amplitud de las variaciones, tratándose del costo total, aumenta igualmente y por idénticas razones.

**10. Y del mismo modo,** en una línea de regular longitud que una varios centros populosos entre sí, el costo de las estaciones, de estilo moderno, puede igualar al costo del resto de la construcción; mientras que en una línea muy larga que pase por muchos poblados de menor importancia o que dependa principalmente del tráfico industrial o de minerales, el costo de las estaciones puede resultar relativamente insignificante.

**11. Comisión del Comercio Interior.** — Por decreto aprobado en marzo de 1913 en el Congreso, se mandó fijar, respecto de todas las propiedades ferrocarrileras :

(1) Su costo original, hasta la fecha;
(2) Su costo de reproducción, nueva;
(3) Su costo de reproducción, nueva, menos la depreciación.

**12. Diferencias de presupuesto.** — Como puede suponerse, se nota generalmente una sensible diferencia entre (a) presupuestos preparados por una compañía con el objeto de mostrar un valor elevado, como en casos de probable venta o cuando se desea justificar las tarifas de carga o pasajeros, y (b) presupuestos preparados por la misma compañía con el fin de mostrar un valor bajo, como cuando se trata por ejemplo de pagar contribuciones, etc. Véase ¶ 139.

**13. « Gastos Generales ».** — Además del costo de construcción propiamente dicho, existen partidas de costo por administración, negociaciones, servicios legales, seguros, impuestos, deterioros, etc. (Véase III. Gastos Generales. ¶ 18.), que afectan el avalúo de toda propiedad, del mismo modo que cuando se trata de impuestos. Semejante avalúo puede debidamente comprender las ganancias que la instalación rinde, que como es natural pueden ser a su vez afectadas por consideraciones completamente ajenas al costo de construcción. Por ejemplo, las propiedades comerciales del territorio atravesado bastarían a dar un alto valor a una vía de reducido costo; o pueden, en cambio, ser tales que la vía más costosa pierda todo su valor.

**14.** Lo único que aquí puede ensayarse como útil, es proporcionar algunos informes o datos (sacados de documentos oficiales) que tiendan a facilitar el cálculo del costo preliminar de una línea en proyecto, teniendo en cuenta las indicaciones y precauciones que preceden.

**15. Costo de unidad.** — Al calcular el costo de las construcciones ferroviarias, deben considerarse :

(1) Los costos de unidad (por yarda cúbica de declive; por acre de limpia; por pie lineal de túnel, etc.) y
(2) los costos por milla, costos por milla de línea o vía sencilla.

**16. Milla de línea contra milla de vía.** — Cuando se trata de calcular el costo por milla, es necesario distinguir entre :

(1) El costo por milla de línea (o milla de camino) (costo de milla lineal)

$$= \frac{\text{costo total}}{\text{número de millas de línea principal y ramales}}$$

(cualquiera que sea el número de vías ó desvíos) y
(2) El costo por milla de vía.

$$= \frac{\text{costo total}}{\text{número de millas de la vía}}$$

**17.** Por consiguiente un camino de doble vía, que tenga $L$ millas de largo, sin vías derivadas, tiene $L$ millas lineales y $2\,L$ millas de vía.

*En cualquier caso*, la milla de vía simple $\leqq$ que la milla de línea ó camino.

Para una línea de vía simple, sin ramales ni desvíos tenemos : costo de vía simple = costo de la línea.

Para cualquier vía doble sin ramales ni desvíos tenemos :

Costo de milla de línea o camino = 2 × costo de vía simple; pero el costo de una línea de ferrocarril de dos vías (en igualdad de otras circunstancias) es *menos* del doble de una línea de una sola vía.

## Clasificaciones de la C. C. I.

**18.** Condensamos a continuación la Clasificación de los gastos de instalación y equipos de los caminos de hierro a vapor, prescritos por la Comisión del Comercio Interior de acuerdo con la Sección 20 del Acta para Regular el Comercio; hecha efectiva en julio 1.º de 1914.

**Cuentas Generales.**

I. Vía o camino. « Costo del terreno, mejoras fijas, máquinas y útiles para el servicio de trasporte. »

II. Equipo. « Costo de las diversas clases de equipos necesarios al tráfico ó necesarios para la explotación del negocio. »

III. Gastos Generales. « A éstos van las erogaciones relativas a las adquisiciones y construcciones de la vía original y su equipo, y de ampliaciones, adiciones y mejoras de la vía y del equipo, cuandos estas erogaciones no pueden debidamente ser incluidas en algunas de las partidas siguientes, como una parte del costo de alguno de los trabajos especificados. »

**Primeros gastos.**

**I. Vía.**

1. Ingeniería.

Comprende : « El pago de los gastos de ingenieros, asistentes, escribientes, empleados en el trazado y construcción de nuevas líneas y extensiones de las subsistentes, ó en adiciones y mejoras incluyendo andenes y muelles.

2. Terrenos para trasportes.
Comprende : « El costo de terrenos para dar ancho a la via; para las estaciones, oficinas, tiendas y otros terrenos; para dar entrada y salida a ciertos lugares; para tener la propiedad de los pozos; sitios de desechos, palizadas para nieves, para arena y otras necesidades; para almacenes de materiales, derechos de la via; el costo de terrenos para apeaderos y muelles y el costo de terrenos ribereños ó con derechos al agua; el costo del derecho de paso y de remover las propiedades de otros a otros lugares y el derecho a estos nuevos terrenos, cuando estos gastos se calculan en el trasporte. »

3. Nivelación.
Comprende : « El costo de limpieza, despejo y nivelacion de la via y el de construccion y protección de caracter permanente, de la calzada, via, terraplenes y desmontes. »

4. Tuberia para fuerza, bajo tierra.

5. Túneles y vias subterráneas.
Comprende : « El costo de tuneles y vias subterraneas, incluyendo el trabajo de ventilación y alumbrado y trabajos de seguridad, distintos al de señales. »

6. Puentes, pilas (torres, etc.) y alcantarillas.
Comprende : « El costo de la sub y superestructura de puentes, pilas y alcantarillas para el paso sobre cursos de agua, barrancos, quebradas, caminos públicos y privados y sobre otros ferrocarriles. »

7. Construcciones elevadas.
Comprende : « El costo de las construcciones elevadas y las fundaciones de las estructuras para ferrocarriles elevados, que no sean trabajos de tierra y que están, para el propósito de vias elevadas sobre la pendiente de las calles y que no son propiamente clasificables como puentes ó torres.

8. Traviesas.

9. Carriles.

10. Otros materiales de via.
Comprende : « Placas, etc., contra resbalamientos, postes y sistemas de sujeción para choques, cruceros, descarriladores, contracarriles, abrazaderas, bridas (uniones), placas de asiento, clavos, desvios, etc. »

11. Balasto.

12. Colocación y preparacion de la via.

13. Derecho de palizadas.

14. Palizadas para nieve y arena. Sostén de terraplenes.

15. Cruceros y señales.

Exclusivos « para cruces de linea en pendientes »; para esto, véase número 10.

16. Estaciones y otros edificios.

17. Edificios en la via.

18. Estaciones de agua.

19. Estaciones carboneras.

20. Tiendas y casa de locomo.

21. Elevadores de granos.

22. Almacenes y depósitos.

23. Andenes y muelles.

24. Andenes para carbón y minerales.

25. Plantas generadoras de gas.

26. Lineas de telégrafos y teléfonos.

27. Señales y cruces.

28. Diques, canales, y tuberias.

29. Planta generadora de fuerza.
Comprende : « El costo del edificio... » Véase nº 45... adelante.

30. Subestación de fuerza.
Comprende : « El costo de los edificios para la transformación de la fuerza... » Véase n.º 46, mas adelante.

31. Sistemas de transmisión de fuerza.
Comprende : « El costo de los sistemas de transmisión a alta tensión... usados para transferir la fuerza que produce la planta al lugar donde se va a transformar... »

32. Sistemas de distribución de fuerza.
Comprende : « El costo de los sistemas de distribución... para llevar la fuerza eléctrica a baja tensión de las plantas que las producen ó de las estaciones donde se transforman y para llevar el vapor ó el aire comprimido de las plantas productoras al lugar donde se emplean... »

33. Pértigas, postes, etc.

34. Conductos subterráneos.

35. Estructuras varias (Miscelánea).

36. Pavimentacion.

37. Maquinaria de via.

Comprende : « calderas, carros (carros de mano; palancas, motores de inspección, de empuje, etc.), mezcladoras de concreto, escavadoras, dragas, máquinas portátiles, niveladoras, maquinaria hidráulica, martinetes, clavador de estacas, descargadores, perforadoras de roca, cilindros de vapor (pisones), etc. »

38. Herramienta menor de via.

39. Apartado para mejoras.

40. Ingresos y gastos durante la construccion.

41. Costo de caminos.

42. Reconstruccion de caminos.

43. Otros gastos. Caminos.

44. Almacen de materiales para máquinas.

45. Planta para maquinaria para la fuerza.

46. Subestacion de aparatos para fuerza.

47. Materiales de construccion y repuestos sin aplicación.
(Los números 48 al 50 en blanco.)

**II. Equipo.**

51. Locomotoras de vapor.

52. Otras locomotoras.

53. Carros de carga.

54. Carros de pasajeros.

55. Equipo de motores para carros.

56. Equipo flotante.

57. Equipo de trabajo.

58. Miscelánea (equipo).

(Nos 59 a 70 incl. en blanco.)

**III. Gastos Generales.**

71. Gastos de organización.
72. Oficiales y empleados.
73. Legislación (parte jurídica).
74. Efectos de escritorio é imprenta.
75. Impuestos.
76. Intereses durante la construccion.
77. Otras erogaciones. Generalidades.

.....
.....

# DATOS DEL COSTO

## CUENTAS GENERALES, I. VIA O CAMINO

### Primeros gastos. Cuenta 1
### Ingeniería.

**Levantamiento.**

**19.** En « levantamiento » incluimos reconocimientos, levantamientos preliminares y trazado y algunos otros trabajos de ingeniería que pueden necesitarse antes de empezar la construccion.

**20. Importante.** — La adopcion de una linea en condiciones de inferioridad, implica aumento de gastos de construcción, ó aumento del costo de explotación por cada tren, durante la existencia de la línea, ó ambos. El costo del levantamiento (trabajo de agrimensura) será generalmente mucho $<$ 1 % del costo total de la linea y es una economia muy insignificante (sobre todo en líneas de importancia) restringir los gastos del levantamiento.

**21. Reconocimientos.** — Estos consisten en una exploración de las *áreas*, mas que de las *líneas*. La comision se compone generalmente de un ingeniero en jefe, un ingeniero para el tránsito (trazador), un topógrafo, un dibujante, un auxiliar para la mira, uno ó mas hacheros y un cocinero, si se necesita y el gasto mensua será entre $750 (dólares) y $1,500 segun la importancia de la linea; pero el tiempo necesario para los reconocimientos, varia entre amplios límites con la importancia de la linea y la naturaleza y condiciones de los terrenos, sobre todo con el número de las líneas que parezcan prestarse a estudio. El costo de los reconocimientos varia por tanto ampliamente; pero probablemente, rara vez excederá de $25 a $50 por milla de linea construida ó digamos de 0.10 % a 0,25 % del costo de construcción.

**22. Levantamiento preliminar y localización.** — La comisión se compondrá generalmente de :

| | Sueldos $/mes. |
|---|---|
| Ingeniero localizador | 125 a 175 |
| — auxiliar | 100 a 125 |
| — del Tránsito | 85 a 100 |
| Nivelador | 80 a 90 |
| Topógrafo | 70 a 100 |
| Dibujante | 70 a 90 |
| Auxiliar para la mira | 50 a 65 |
| Cadeneros; 2 a $40 ó $50 | 80 a 100 |
| Peon para bandera atrás | 30 a 40 |
| — la cinta; 1 ó 2 de $30 a $45 | 30 a 90 |
| — estacas (estaquero) | 30 a 35 |
| Hacheros, 2 á 5, de $25 a $30 uno | 50 a 150 |
| Total : 14 a 18 hombres | |
| Sueldos de la comision por mes cuando el jornal vale $1,50/hombre/dia | $800 a $1,600 |

.....

.....

**23. Los trabajos (topográficos), de levantamiento por milla de linea construida** pueden llegar a valer tres y cuatro veces los del trazado de la linea ya indicados.

**24.** El costo de la milla de linea de levantamiento depende de las condiciones de los terrenos y de las limitaciones impuestas como máximo de pendientes y máximo de agudeza en las curvas.

**25.** Una planicie poco accidentada ó una linea faldeando un rio que ofrezca pocas dudas en la eleccion de una linea necesitará pocas millas de estudio preliminar en relación con las millas de construccion definitiva comparado con las que necesitará una linea que atraviese una region escabrosa, quebrada que exija el estudio de varias lineas favorables para encontrar la mejor. En esta clase de terrenos, por supuesto que las restricciones en las pendientes y en la agudeza de las curvas aumenta el gasto de trabajos topográficos por milla construida.

**Ingenieria.**

**26. Costo probable** de este ramo deducido de la comparación de diez y ocho costos en diversas lineas :

| | $/milla de linea. | % del costo total de constn. |
|---|---|---|
| Gastos preliminares y estudio de la linea.. | 150 a 400 | ½ a 1 |
| Gastos de ingenieria durante la construcción (vigilancia trabajos, superintendencia, etc.)..... | 400 a 1,300 | 1.5 a 3 |
| Total..... | 550 a 1,700 | 2 a 4 |

## Primeros gastos. Cuenta 2.
## Terrenos para Transportes.

**Bienes raices.**

**27.** Quizás este es el capitulo en que se requiere mas previsión cuando se quiere deducir el costo de una linea del de otras existentes y al tratar de los derechos y propiedad de las vias, estaciones, terminales, derechos de agua, etc., etc.

**28. El precio por acre** puede variar de $10 y hasta menos en tierras sin valor a $20,000 ó mas en terminales de ciudades; y el costo en estos sitios puede crecer rápidamente de acuerdo con el desarrollo de las ciudades. Indudablemente que, muchas veces los terrenos *se ceden gratuitamente* a las compañias por el gobierno ó por los interesados en el desarrollo del comercio bajo la acción de una linea que atravicee el pais; y por otra parte tambien se dictan previsiones para contrarrestar la demanda de precios excesivos por algunos dueños llenos de avaricia; otras veces las compañias suelen pagar estos precios antes que recurrir a una expropiación que trae litigios y que obligan a la compañia a restricciones, en cuanto al uso exclusivo de los terrenos para asuntos del ferrocarril y asi suelen costarle a la compañia de 2 á 5 veces el valor comercial de las propiedades adyacentes.

**29. El ancho de la via propia** puede variar de 50 pies (como 15 m) ó menos para una linea económica de una sola via en terrenos llanos a 200 pies (como 60 m) ó mas para una linea principal de poca pendiente, de dos a cuatro vias, desmontes profundos y terraplenes altos. El area y los precios de los terrenos necesarios, para patios, estaciones, etc., varia ampliamente con la naturaleza del tráfico.

1 acre por milla = 8.25 pies (como 2.5 m) ancho linea;
66 pies (como 20 m) ancho = 8 acres por milla (2.008 hectareas por kilom);
100 pies (30,5 m) ancho = 12.12 acres por milla (3.042 hectareas por kilom).

**30. La relación**, entre el costo del terreno para la Cia de Ferroc y el valor en plaza del mismo para usos ordinarios, se llama el « *múltiplo del costo del terreno para la via* ».

**31. Adquisiciones.** — Esta materia es muy complicada por el hecho de que las compañias de ferrocarriles frecuentemente compran una zona ó faja mucho mayor de la que necesitan para su linea, esperando vender el excedente a precios muy superiores como consecuencia de la construccion de la via y otras veces obligados a ello como concesiones a propietarios recalcitrantes que no venden lotes menores.

.....

.....

## Construcción del lecho de la vía.

**32.** Esta construcción (la preliminar para situar la vía) puede considerarse incluida en C. C. I., cuentas 3 á 7 inclusive (véase ¶ 18). Se compone principalmente de la 3, Nivelacion (incluyendo limpieza, desyerbo); Cuenta 5, Túneles y vias subterráneas; Cuenta 6, Puentes, etc.

**33.** Dando el costo por unidad, de materiales y obra de mano, el costo por milla de trazado y de vía de cada una de las materias incluidas en « Lecho para la vía » varía entre muy amplios límites. Así una linea en llano, no necesita túneles, puentes, pilas y poca ó ninguna nivelacion, mientras que en terrenos dificultosos casi toda la linea puede necesitar rozas fuertes, desmontes, terraplenes y quizas túneles, alcantarillas, y puentes con alguna frecuencia; especialmente donde la tendencia moderna a reducir el costo de explotación, suavizando las pendientes y el alineamiento, obliga a desmontes mas profundos y hace mas frecuentes los puentes, alcantarillas, etc.

## Primeros Gastos. Cuenta 3.
## Nivelación.

**34.** La nivelación incluye, desyerbos, rozas, represas, desmontes, terraplenes, en puentes, calzadas y sobre alcantarillas, pilas, trabajos con la pala de vapor, muros de revestimiento y de sostenimiento, fosas, compuertas, etc.

### Desyerbos y rozas.

**35.** Estos trabajos estan a veces incluidos en los de nivelación; pero los desyerbos y rozas se calculan a veces aparte, porque frecuentemente solo en una parte del terreno se necesitan. Los troncos y raíces se dejan debajo de los terraplenes, a menos que éstos sean poco profundos.

. . . . . .

. . . . . .

**36. Elementos que afectan el costo.** — El costo por unidad de area, de las rozas, depende de la densidad del monte, de la especie y tamaño de los árboles y del monte bajo, de la naturaleza y accesibilidad del terreno y de las facilidades para mover y sacar los materiales. Este costo puede ser disminuido ó compensado y hasta excedido por el valor de la madera que se saque. Tambien depende aquel costo del método que se emplee en los trabajos de nivelacion. Así por ejemplo una pala de vapor (en tierra) ó una perforadora en roca, pueden hacer gran parte del trabajo que corresponde a las rozas y tumbas. Por otra parte el uso de los arados en desmontes exige tumbas y rozas cuidadosas.

**37.** El costo de la milla de linea por roza y tumba, depende del área por milla de linea y ésta, a su vez del ancho de la zona donde va la linea y de la parte de ésta ocupada por árboles y monte.

| | | | | | |
|---|---|---|---|---|---|
| 1 | 5 | 8.25 | 10 | 16.5 | pies de ancho = |
| 0.1212 | 0,606 | 1 | 1.212 | 2 | acres por milla. |
| 0.30 | 1.52 | 2.59 | 3.05 | 5.03 | metros de ancho = |
| 0.0303 | 0,151 | 0,251 | 0,303 | 0,50 | hect por kilómetro. |
| 20 | 24.75 | 30 | 33 | 40 | 41.25 | pies de ancho = |
| 2.424 | 3 | 3.636 | 4 | 4.848 | 5 | acres por milla. |
| 6.10 | 7.55 | 0.14 | 10.06 | 12.19 | 12.57 | metros de ancho = |
| 0.606 | 0.75 | 0.909 | 1 | 1,212 | 1.25 | hect por kilómetro. |
| 49.5 | 50 | 82.5 | 100 | 165 | 200 | pies de ancho = |
| 6 | 6.06 | 10 | 12,12 | 20 | 24.24 | acres por milla. |
| 15.08 | 15.24 | 25.14 | 30.48 | 50.29 | 60.96 | metros de ancho = |
| 1.50 | 1.515 | 2.50 | 3.03 | 5 | 6.06 | hect por kilómetro. |

**38. Generalmente** de 1 a 6 acres por milla (0.25 a 1.50 hect por kilómetro) ó sea una faja de (8.25 a 49.5 pies ó de 2.59 a 15,08 metros) requieren limpia y tumba.

**39.** El sitio de Brockton, Mass, tiene 480 árboles de (15 a 50 cm de diámetro) por acre = un árbol por cada 91 pies cuad = un arbol por cada 8.50 met cuad. Es muy denso.

**40.** El costo de limpia y tumba puede ser generalmente el siguiente :

| | Tumba. | Roza. | Ambas cosas. |
|---|---|---|---|
| Por arbol ó tronco..... | $1 á 2 | $0.05 á 1 | $1 á 3 |
| Por acre (0.40 hect)..... | $25 a 150 | $25 a 150 | $50 a 300 |
| Generalmente calculada por. | ..... | ..... | $50 |
| Por milla de linea..... | $50 a 600 | $50 a 300 | $100 a 1000 |

### Movimiento de tierra.

**41.** La « nivelación » propiamente incluye (ademas de la limpia y tumba) los « trabajos de tierra » ó sea la excavación, trasporte, depósito y apisonado de tierra, en sus varias formas y de cascajos, capas consistentes, cimientos cascajosos, piedra suelta y rocas sólidas. Cuando los desmontes no dan tierras suficientes para los rellenos y terraplenes se toma el material en fosas y zanjas y este trabajo se acostumbra clasificarlo como « terraplenes ».

**42. Elementos que influyen en el costo.** — El valor de la unidad cúbica de los movimientos de tierra varia mucho con la naturaleza del material, con su accesibilidad, con las cantidades, con las facilidades para manejarlo con la pericia del contratista, con el costo de los salarios, pero sobre todo con la distancia a que debe ser trasportado. Veanse pags 1092 á 1106. En cualquier trabajo de consideración, sinembargo los trasportes largos y cortos se considera que se compensan y es costumbre contratar a un precio fijo el metro ó yarda cúbica de las diferentes clases de material que se encuentren, con un límite especificado para la longitud del arrastre, mas allá del cual el contratista paga (generalmente un centavo por yarda cúbica (1.30 por met cúb) por cada 100 pies (como 30 m) de exceso en la distancia.

**43. Costo por milla.** — Para un precio por unidad cúbica el costo por milla de los movimientos de tierra varía entre límites muy separados, dependiendo de la cantidad que se necesita por milla, la que a su vez depende de las condiciones del terreno y de la necesidad de pendientes y trazados favorables en la linea final; una región dada, naturalmente requiere mas movimientos de tierra para una linea de pendientes y curvaturas limitadas que para otra donde las pendientes fuertes y las curvas agudas y largas, son permitidas.

.....

.....

### Primeros Gastos. Cuenta 5.
### Túneles y vias subterráneas.

**Túneles.**

**44. Elementos que influyen en el costo.** El costo de los túneles por unidad cúbica depende de la naturaleza del material que hay que extraer y de las facilidades para extraerlo; de la necesidad de revestirlos y la naturaleza del revestimiento; de la cantidad de agua que se encuentra y la facilidad de sacarla, de lo accesible de su situación para los trabajos; del costo del jornal; de la pericia del director de los trabajos, etc. Se hacen menos por contrato que por salarios, auxiliados por las compañías que proporcionan las fuerzas. En los túneles largos, debido a los largos arrastres, a la necesidad de hacer chimeneas de tiro por la dificultad de la ventilacion y al mayor costo (por sus condiciones) de la planta necesaria, resulta generalmente (en igualdad de otras condiciones) el costo mayor que en los túneles cortos. Es menor para *la mesa* (parte baja) que para la galeria (parte cilíndrica); y, por la misma razón (especialmente en secciones pequeñas) disminuye cuando se aumenta el area de la sección.

.....

## Primeros Gastos. Cuenta 6.
## Puentes, Pilas, Alcantarillas.

**45. Peso del acero.** — La fórmula que sigue de la linea recta, para pesos del acero en la superestructura de puentes de ferrocarril de una via, incluyendo los sistemas de pisos, está extractada de la de los Sres J. B. Johnson y H. G. Tyrrell G. 1471, 1474. Para puentes de ferrocarriles de doble via agregúese el 90 %. Véanse muestras pags 790, 797 y 798.

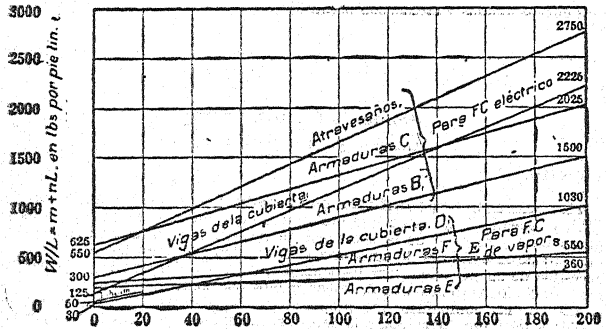
$$W = L\ (m + n\ L)$$

en donde $W$ = peso de la estructura en libs; $L$ = luz en pies; y $m$, $n$ = coeficientes como sigue.

| Puentes para | Diferencias notas abajo. | $m$ | $n$ |
|---|---|---|---|
| Carreteras..... | *A* | 50 | 2 |
| Ferroc. de vapor : | | | |
| Vigas laminadas de la cubierta..... | | 100 a 150 | 9 a 12 |
| Traviesas..... | | 500 a 600 | 10 a 12 |
| Armadura de puentes..... | *B* | 200 a 400 | 5 a 7 |
| | *C* | 600 a 650 | 7 |
| Ferroc eléctricos : | | | |
| Vigas en I (luz de 5 a 20 pies = 1.52 a 6.10 m)..... | | 50 | 5 |
| Vigas laminadas de la cubierta..... | *D* | 30 | 5 |
| Armaduras remachadas..... | *E* | 200 | 0.8 |
| | *F* | 250 | 1.5 |

*A.* Carga viva 100 lbs/pie cuad (488 kg/m cuad). Agréguese 15 lbs/pie de lu (23 kg por metro de luz) por cada 0 m. 60 de variacion desde 5 m de ancho de l carretera.

*B.* Para 2 loco de 100 ton y 4.000 lbs por pie lineal (5952 kg por m lineal) de tren.



*Las lbs se convierten en kgs multiplicándolas por 0.453 y las lbs por pié en kgs por metros multiplicandolas por 1.486.*

**Fig. 1.**

*C.* Para luces de 30 a 230 pies (9.15 a 70.00 m). Carga Cooper E-50 (pag. 818); dos loco 177.5-ton y 5000 lbs por pie lineal (7440 kg por m lineal) de tren.

*D*. Carga viva, 2.000 lbs/pie lineal (2976 kg/m lineal).
*E*. — 1.000 — (1488 kg/m lineal); carros de 15 ton; luz de 40 a 200 pies (12 a 60 m).
*F*. Carga viva; 2.000 lbs/pie lineal (2976 kg/m lineal); carros de 30 ton; luces de 20 a 180 pies (6 a 54 m).

**46.** La fig. 1 muestra, aproximadamente, para cada clase el valor medio de $W/L = m + n\,L$ = peso/pies de luz, en la superestructura de puentes de ferrocarril, como lo da esta ecuacion.

**47. Para pilas, arcos y estribos** para puentes de ferrocarriles a vapor, agréguense 9 lbs/pie cuad (44 kg/m cuad) del perfil del area del terreno a la base del carril; para ferroc eléctricos las $^2/_3$ partes.

**46.** Cantidad de madera en las pilas incluyendo 164 pies de tabla por pie lineal (1.270 m cúb de madera por metro lineal) y en las pilas de 4 pilas arqueadas 16 pies (4.88 m) de *c* a *c*, *G*966.

$$F = L\,(m\,H + n) = m\,A + n\,L\,;$$
$$P = L\,(H + 20)/4.$$

donde :

$F$ = total de pies de madera en la construcción;
$L$ = longitud de la pila en pies;
$A$ = perfil del area de la pila en pies cuad desde el terreno hasta 4 pies (1.22 m) bajo la base del carril;
$H = A/L$ = altura media.
$P$ = pies lineales de pilotaje en las pilas;
$m$, $n$ = coeficientes, como sigue :

| | En las partes de la pila | | En las pilas. | | | |
|---|---|---|---|---|---|---|
| Para alturas. | hasta 15′ (4.5 m) | 15′ (4.5 m) a 25′ (7.5 m) | 25′ (7.5 m) | 25′ (7.5 m) a 50′ (15 m) | 50′ (15 m) a 75′ (22.5 m) | 75′ (22.5 m) a 125′ (37.5 m) |
| Coeficientes. | | | | | | |
| $m$ = | 0 | 0 | 6 | 8 | 9 | 10 |
| $n$ = | 185 | 200 | 220 | 240 | 240 | 240 |

. . . . . .

. . . . . .

**Costo de la milla de via.**

**51.** Prácticamente cada milla de via requiere 5280 pies lineales (1609 m) de balasto de traviezas, de colocación y arreglo de superficie y 10,560 pies (3.218 m) lineales de carriles, con sus bridas y demas piezas. Solo el capítulo de desvios está sometido a notables variaciones en el costo de la milla, aun en distintas lineas del mismo carácter general; y estas variaciones son de relativa insignificancia, pues su valor es generalmente de 1 a 3 % del costo total de la via.

**52.** Por tanto, para un costo dado y una construcción dada, el costo por milla de la linea (carriles, etc.) es practicamente constante.

**53. Elementos que afectan el costo.** — Con un material dado el costo de la milla de balasto depende de la seccion transversal de éste; el de las traviezas de su sección y separación el de los carriles y piezas menudas, del peso por unidad lineal de aquéllos; y el de los desvios, de la calidad de su construccion y de su número por milla.

**54. El costo sube.** — Los adelantos en la manufactura (particularmente la hecha en grande escala, la union, consolidacion de sistemas de lineas pequeñas a grandes lineas para su dominio (control) en conjunto y el creciente esfuerzo en el sentido de mayor eficiencia) han producido una reduccion en el costo de la unidad de carril; pero, no ha resultado una grande y progresiva reducción desde 1887; y el costo de la unidad de otros elementos (sobre todo el de las maderas, debido a la escasez) va en aumento. Ademas, el aumento de peso del material rodante y de las cargas han obligado a aumentar la solidez de la construcción. Así pues la tendencia del costo de la via (carriles, traviezas, etc.) es de aumento.

. . . . . .

. . . . . .

## GASTOS GENERALES III

**55.** En este capítulo deben ponerse los gastos, como los relativos a la rganización de las compañias, incluyendo los jurídicos ; los necesarios para obtener los certificados de conveniencia y necesidades públicas (exigidos en algunos estados); los necesarios para obtener franquicias y privilegios; los de compensaciones a los promotores (muchas veces sometidos a graves abusos); los requeridos para emitir y dar curso comercial a las acciones y bonos, incluyendo

autorizaciones oficiales y los descuentos de esos valores que pueden tener que venderse bajo la par. Estos totales varian mucho. Mr Walter Loring Webb (« Construcciones de Ferrocarriles », 1905 pag 394 dice : « Se calcula que mas ó menos 2 % (sobre el valor de los titulos) del capital de los ferrocarriles en la Gran Bretaña, se han invertido en gastos « Parlamentarios ».)

**Cuenta 73 (Legislación) y 76 (Intereses** durante la construcción).

**56.** Las partidas de intereses y de gastos de legislación generalmente alcanzan le 2.5 a 5 % del costo total de construccion, sin entrar el material rodante; pero en estimados y valuaciones de peritos, tratándose de largos periodos en que han trascurrido épocas en condiciones no remunerativas, se ha llegado algunas veces a cifras mucho mayores. Asi en el caso del « Gt Northn Ry Sistem. G 1734, en que el costo, sin equipo, llegó a $56,330/milla lineal, el Ing en Jefe estimó los intereses en $5690/milla lineal y los gastos legales en $563/milla; total $6253/milla lineal.

## CONSERVACIÓN DE LA MADERA

**Art. 1.** (a) **La destrucción de la madera** la causa, el crecimiento y la actividad de los hongos. Los pequeños gérmenes de uno de estos hongos, al desarrollarse en un pedazo de madera, produce unos filamentos delgados, que penetran en sus celdas y á poco producen un fermento que destruye ciertas partes de la fibra de la madera. Esta fibra disuelta sirve de alimento á los hongos. Los filamentos van echando ramas y ramales, y muy pronto la madera se encuentra invadida por una masa de aquéllos, cuyo crecimiento produce más fermento, alterando las propiedades químicas y físicas de la madera y convirtiéndola, á veces, en una especie de carbón parduzco, otras, toda blanca ó blanca y fibrosa, diciéndose entonces que la madera se ha podrido. Por fin algunos de los filamentos salen á la superficie y forman hongos al aire, y otras excrecencias; bajo éstas existen cavidades que contienen millares de gérmenes, á los cuales los arrastra el aire y caen sobre otras maderas, en donde se repite el procedimiento. La humedad y el calor son propicios al crecimiento de los hongos, así como también las féculas, azúcares y aceites que se encuentran en las células de la albura de la madera y que no existen en el corazón. Si se la protegiese de la acción de estos hongos la madera duraría indefinidamente. Por esta razón se debe evitar la acumulación de maderas cortadas. Si se excluye el aire, como cuando se conserva la madera constante y enteramente sumergida en agua salada ó dulce, los hongos no pueden prosperar. La savia conservada en la madera con el aire se fermenta produciendo la *carcoma*, como sucede cuando las vigas quedan herméticamente encerradas en la mampostería de ladrillos, etc., y cuando las maderas verdes se pintan ó barnizan, ó se creosotan, etc.; pues entonces la savia no sólo impide la completa penetración del aceite, etc., sino que hace que la mayor parte de la madera se pudra aun cuando en su superficie presente una apariencia de solidez. (b) Por lo tanto se debe destruir la savia **sazonándola**, ya sea secándola al aire á una temperatura normal ó más alta, ó sometiendo antes la madera á una presión de vapor para evaporar la savia y luego eliminarla por el vacío. Para sazonar completamente grandes trozos de madera al aire seco y á temperaturas ordinarias puede requerirse años. La secada rápida en hornos raja y debilita la madera. Es dudoso si la acción del vapor y del vacío eliminan la savia tan completamente como el procedimiento de seca lenta. (c) La exposición alternada al agua y al aire es muy destructora. Causa la putrefacción húmeda.

**Art. 2. Gusanos de mar.** La *limnoria terebrans* trabaja casi desde el nivel del agua hasta un poco más abajo de la superficie del lodo del fondo; el *teredo navalis* entre límites un poco menores. Se dice que el teredo se hace menos activo con la presencia de las aguas de cloacas.

**Art. 3.** (a) Los mejores procedimientos para conservar la madera son prácticamente **inútiles á menos que sean llevados á cabo al pie de la letra.** Si la ganancia en durabilidad no compensa el gasto de tiempo y dinero que se requieren para esto, es más económico emplear la madera en su estado natural. (b) **Las maderas más apropiadas al tratamiento son aquellas** de fibra abierta y porosas que absorben el aceite, etc., mejor que las maderas más compactas, y su baratura hace la aplicación del tratamiento más productiva. (c) La mayor parte de los sistemas que se emplean más frecuentemente parecen hacer á la madera menos combustible. (d) Después del tratamiento de la madera por cualquier sistema, debe secarse bien antes de usarla.

**Art. 4.** (a) **El aceite de creosota** (*ó dead oil*) es el mejor preservativo conocido. Contra los gusanos de mar es eficaz de 15 á 25 años y es la única protección conocida. (b) Como remedio temporal se cubren las estacas algunas veces con láminas de metal ó con clavos de cabezas anchas muy unidos. Éstos se oxidan ó se destruyen en pocos años. Estacas de roble cortadas en enero y clavadas dejándoles la corteza han resistido á los teredos por 4 ó 5 años; y estacas de ciprés bien chamuscadas, por 9 años. (c) Se necesitan como 144 kg por m cúb para su protección ordinaria en la tierra. Para proteger la madera de los gusanos de mar se gastan 130 kg por m cúb en climas como los de la Gran Bretaña y los Estados Unidos; pero en aguas más cálidas, en que el teredo es muy activo, se emplean 220 kg por m cúb. En trozas grandes puede no necesitar la madera saturación completa y requerir, por tanto, menor cantidad. Pero véase (i) y el final del art. 1 (a). (d) Dicho aceite pesa como 1.04 kg el litro (8.8 lbs. gal). (e) Las piezas deben reducirse á las dimensiones finales que se desee y armarse (si fuese necesario hacerlo) antes del tratamiento; especialmente si van á exponerse al *teredo*, pues éste atacará con seguridad cualquier punto que por corte posterior haya quedado sin protección. (f) Las traviesas creosotadas han soportado sanas hasta 22 años de exposición. La creosota protege los clavos de la oxidación. (g) El abeto y el alerce no se pueden creosotar por razón de su irregular densidad. (h) La creosota endurece la madera y la hace un poco más quebradiza. En época de calor se exuda un poco y descolora. Su olor la excluye de las habitaciones. (i) No se sale de la madera, pero á menudo sucede que no penetra hasta el corazón, y por consiguiente si ha quedado alguna savia comienza á podrirse en el centro. Véase el final del art. 1. (a) Por mucho tiempo se ha tenido como el mejor preservativo, tratarla interiormente con el sistema de Burnett y usar una capa de creosota por fuera (véase art. 7). Ésta es la mayor ventaja que presenta el procedimiento de **Allardyce**. Es más barato que creosotar por completo. En el **procedimiento de Rutgers**, que se ha empleado con éxito en Alemania para las traviesas, desde 1874, se inyectan simultáneamente la creosota y una solución de cloruro de cal. (j) En el **procedimiento de creosotar** *, el fluido preservativo consiste de 38 por ciento de creosota, 2 por ciento de *formaldehyde* y 60 por ciento de resina fundida.

**Art. 5.** (a) **Las soluciones minerales** son inferiores á la creosota, aun en tierra, y completamente inútiles en aguas dulces ó contra el gusano de mar, pero duplican casi la duración de las maderas de calidad inferior colocadas en tierra; su bajo precio permite usarlas en donde la creosota es demasiado cara. (b) Hacen más dura á la madera, y se vuelve quebradiza si la solución es demasiado fuerte. Están expuestas á ser lavadas por la lluvia, etc., y por consiguiente, la capa exterior se pudre primero. Véase art. 4 (i) y art. 8 (b), (c), (d). (c) Una comisión de la Sociedad Americana de Ingenieros Civiles**, después de comparar un gran número de experimentos, recomendaron el sistema de Burnett, **para exposiciones á la humedad** (art. 7), como en traviesas, en pisos húmedos, etc.; y el sistema de Kyan (art. 6) **para exposiciones relativamente secas** con exposición al aire y al sol (como en las vigas de un puente), para las cuales es más apropiado que el sistema de Burnett, porque parece debilitar menos la madera. En semejantes casos conserva la madera de 20 á 30 años.

**Art. 6.** (a) El sistema de Kyan consiste en sumergir la madera en una solución de 1 por cien de agua de **bicloruro de mercurio (sublimado corrosivo)**. (b) Generalmente se hace que la madera se remoje un día por cada 25 mm de la menor dimensión de la pieza, y un día más cualquiera que sea el tamaño. (c) El general Cram encontró el procedimiento muy *malsano* porque producía « salivación » á los obreros, pero B. Francis, en Lowell, y H. Bissell, del ferrocarril del Este de Massáchusets, encontraron poco ó ningún inconveniente á este respecto. Sin embargo, el sublimado, que es muy venenoso, tiende á esflorecer, y el uso de la madera se hace, por tanto, peligroso. (d) El procedimiento es valioso para las maderas colocadas en lugares moderadamente húmedos, pero la sal está expuesta á ser lavada por el agua corriente. El abeto tratado por el sistema de Kyan empleado en postes de cercas, clavados á 1.20 m de profundidad, en Lowell, Mass., en 1850, fueron examinados en 1891, y la mayor parte se encontraron en buen estado tanto sobre como debajo de la tierra.

**Art. 7.** (a) El sistema de Burnett consiste en sumergir la madera durante algunas horas en una solución de 2 por ciento de *cloruro de cinc*, bajo una presión como de 7 á 21 kg por cm cuad.

* Véase « Método propuesto para la conservación de la madera », por F. A. Kummer rans. Am. Soc. C. E., vol. XLIV, diciembre 1900.

T** Véase Trans. Am. Soc. C. E., julio, agosto y septiembre 1885.

**Art. 8. Otros preservativos.** (a) Se ha usado mucho el de sumergir la madera en una solución de **sulfato de cobre** (**vitriolo azul**), pero parece que no ha dado siempre buenos resultados. El vitriolo azul lo suelta fácilmente. (b) En el procedimiento de Barschall ó Hasselmann §, introducido en Alemania en 1887, y en los Estados Unidos en 1899, se hierve la madera á una temperatura de 100° á 140° C y bajo una presión de 1 á 3 kg por cm cuad, en una solución de sulfatos de hierro, cobre, aluminio y de « Kainit », un sulfato de magnesia y potasa, extraído de las minas de Stassfurt, en Alemania. Se dice que la solución arrastra la savia (la madera se trata más fácilmente por este procedimiento cuando está verde), y que el cobre destruye los hongos, y el hierro forma un compuesto insoluble con la celulosa ó fibra leñosa. También se asegura que el procedimiento endurece mucho la madera, especialmente las clases blandas, haciéndolas útiles para traviesas, sin disminuir su resistencia, elasticidad y flexibilidad. (c) En el **procedimiento de Wellhouse** se inyecta primero una solución de cloruro de cinc con cola y luego una de tanino (ambas bajo presión), á fin de disminuir el consiguiente arrastre del cloruro. En una modificación posterior, las soluciones de cinc, cola y tanino se inyectan separadamente. De esta manera se han tratado algunos millones de traviesas No se recomienda este procedimiento para maderas que se emplean bajo el agua. (d) Los procedimientos en los cuales se trata la madera por **pintura** ó **inmersión** *, son : Carbolineum America (C. A. preservador de Maderas) y Carbolineum Avenarius (esencia de alquitrán, cloro, etc.), Ligni Salvor (esencia de alquitrán, etc.), Woodiline y Spiritine (soluciones químicas) y un destilado de pino, empleado por el ferrocarril de Pensilvania en la construcción de vagones. (e) Parece que los postes de cercas, etc., se conservan hasta cierto punto con sólo sumergir su extremo inferior en **alquitrán** bien hervido, para quitarle el amoníaco que destruye la madera. El extremo superior se deja sin alquitranar para que se evapore la savia. (f) Los experimentos hechos para conservar la madera por medio del *vapor de la creosota* han resultado ineficaces. (g) Mientras la madera se conserve completamente saturada de **petróleo** no se pudre, pero hay que petrolizarla á menudo, pues al evaporarse la deja sin protección. (h) Las traviesas de madera de algodonero colocadas en un **terreno** que contenga un 2 por ciento de carbonato de cal, 1 por ciento de sal y .5 por ciento de potasa y óxido de hierro, en el ferrocarril Union Pacific, en 1868, se encontraron en 1882 « tan sanas y mucho más fuertes que cuando se colocaron », y las mismas traviesas en otros terrenos tan sólo duraron de 2 á 5 años. (i) El empleo de soluciones de **cal y sal**, así como el chamuscar la superficie, es á veces útil en lugares húmedos.

§ Railroad Gazette, febrero 9, 1900.

* Véase el Informe de O. Chanute á la Am. Ry. Eng. and Maint of Way. Assotion, de marzo 1901.

## Art. 4. Término medio de la resistencia máxima á la tensión, ó cohesión de las maderas.

Esas son las cargas más pequeñas en kg que, colocadas en el extremo inferior de una varilla vertical de 6.45 cm cuads de sección, y bien fija en el extremo superior, la romperían separándola ó rasgándola en pedazos. Para largas piezas de madera recomendamos reducir estas constantes en ¼ á ⅓ parte.

(*Obs. del T.* — Hemos convertido la tabla del autor al sistema métrico.)

| Las resistencias en todas estas tablas pueden ser una tercera parte mayor ó menor que nuestros términos medios. | Kg por cm cuad. | Las resistencias en todas estas tablas pueden ser una tercera parte mayor ó menor que nuestros términos medios. | Kg por cm cuad. |

| Locust (algarrobo, acacia, etc.) | 1,265 | | |
| Arce | 703 | | |

**Estos son términos medios.** Las resistencias varían mucho con la edad del árbol, el lugar en que crece, según la pieza sea del corazón ó de las capas exteriores, con el grado de sequedad, rectitud de sus fibras, nudos, etc., etc. Además, como las constantes se deducen de ensayos hechos con buenos materiales de tamaño pequeño, mientras que las vigas grandes son más ó menos defectuosas por los nudos, por la sinuosidad de sus fibras, etc., es conveniente, en la práctica, reducir estas constantes como se recomienda arriba.

* **Efecto en los árboles de la extracción de la trementina.** Los experimentos preliminares hechos por la Sección de Selvicultura, del Departamento de Agricultura de los Estados Unidos, en pino de hojas grandes de Alabama, indican que (contra la opinión general) « la madera de las terebintáceas » ó sea la madera de los árboles á que se les ha extraído la trementina, aunque tienen ligeramente menos resistencia á la tensión y al esfuerzo cortante, presentan de 20 á 30 por ciento más de resistencia á la compresión (ya sea en el sentido ó transversalmente á las fibras) y bajo la acción de esfuerzos transversales. En dicha madera, sin embargo, la resina se acumula en ciertos puntos, y embotando ó engomando los instrumentos, se hacen más difíciles para labrarlas que las que provienen de árboles que no se les ha quitado la trementina. Los trozos probados se cortaron, en su mayor parte, á alturas desde 1.13 m hasta 10 m sobre el suelo (circular n.º 8 publicada en 1892). Las maderas á que se les ha extraído ó no la resina se llaman frecuentemente « sangradas » ó « sin sangrar ».

**Art. 1. Resistencia á la compresión de las maderas americanas,** *cuando han sido secadas lenta y cuidadosamente.* Promedios aproximados deducidos de muchos ensayos hechos con la máquina de probar maderas del Gobierno de los E. U., en Watertown, Mass, por S. P. Sharples, para el censo de 1880. **Las maderas secas** resisten mucho más que las verdes la trituración; en muchos casos hasta el doble. Esto debe tenerse presente al construir puentes, etc., con maderas recién cortadas. Diversas muestras de la misma madera se diferencian mucho entre sí, frecuentemente como 5 á 8, 9 ó más.

(*Obs. del T.* — Hemos convertido la tabla que trae el autor al sistema métrico.)

| La resistencia en todas estas tablas puede variar fácilmente hasta 1/3 más ó menos de nuestro promedio. | Por los extremos*, kg por cm cuad. | Por los lados**, kg por cm cuad. | |

* Muestras de 4 cm en cuadro, 32 cm de largo.

** Muestras de 4 cm en cuadro, 16 cm de largo, puestas en la plataforma de la máquina de prueba. La presión aplicada en mitad de su longitud, por medio de una perforación de un gancho de hierro de 4 cm en cuadro, es decir, lo suficiente para cubrir todo el ancho de la muestra y un cuarto de su longitud. La primera columna de la tabla enca-

De lo anterior aparece que el pino blanco y el amarillo, el abeto y el roble común, **secos**, que son las maderas más usadas en los Estados Unidos para puentes, techos, etc., se trituran longitudinalmente con 350 á 490 kg por cm cuad, **en pequeños bloques**, dando un promedio de 420.

Pero es conveniente recordar que en la práctica es raro obtener presiones perfectamente distribuídas. En algunos ensayos de compresión lateral, hechos con bloques de pino blanco, de 15 cm de alto, 12½ de largo y dos de ancho, se encontró que bajo una presión, igualmente distribuída, de un total de 2,265 kg ó 350 kg por cm cuadrado, comprimían de 3 á 6 mm, lo que es igual, más ó menos, á $^1/_{48}$ á $^1/_{24}$ de la altura, siendo el promedio de unos 3 por ciento de la altura. Bajo 4,535 kg de carga total, ó 70 kg por cm cuadrado, se astillaron por completo, y en algunos casos saltaron grandes pedazos.

La resistencia á la tensión ó la cohesión del pino y del roble es de un promedio de 703 kg por cm cuad, ó la mitad del promedio del hierro colado, ó casi el doble de su resistencia á la trituración. La resist á la tensión no varía con el largo de la pieza; de manera que en la práctica se puede tomar como de seguridad una fuerza como de 70 á 140 kg por cm cuad, dependiendo de la naturaleza de la construcción, etc., sin tomar en cuenta la longitud, excepto cuando ésta es tan grande que hay que empatar una ó más piezas para formarla, debilitando mucho la pieza de esta manera.

---

**Tabla de cargas de seguridad, estática só en reposo, de vigas rectangulares horizontales de pino blanco ó abeto de 25 mm de ancho apoyadas en ambos extremos y cargadas en el centro, y de la flexión, producida por dicha carga.**

Estas cargas de seguridad son una sexta parte de las cargas de ruptura.

**Para obtener la carga neta**, dedúzcase ½ del peso de la misma viga. La *flexión*, no obstante, es la *verdadera;* el peso de las vigas se ha introducido al calcularla.

**Las cargas aplicadas repentinamente** duplicarán las flexiones dadas en la tabla, como cuando, por ejemplo, se sostiene un peso en la mano, de modo que se halle en *contacto* con una viga, y se suelta repentinamente.

**Advertencia.** Como esta tabla se basa en piezas de fibras derechas bien secas, sin nudos ni otros defectos, no debemos tomar en la práctica más de dos tercios de las cargas dadas en la tabla para cargarlas con un coeficiente de seguridad igual á 6 en las construcciones ordinarias de madera de buena calidad; y con estas cargas reducidas *no* se deben reducir las flexiones *.

**Obsérvese también que** nuestra tabla es para cargas de seguridad **centrales**; pero es claro que en la práctica no podemos aplicar siempre el término con sumo rigor, pues de otra manera la carga tendría que estar sostenida por el filo de una cuchilla para que se hallase aplicada en el *verdadero centro* de la viga; ahora bien, en el ejemplo de la nota pág. 1055, si pretendiéramos sostener la carga central de 6,075 lbs (2,756 kg) en un filo de cuchilla, en el acto cortaría la viga en dos. Si siquiera la aplicamos en una extensión de 8 á 10 cm de su longitud, siempre penetraría en la viga cortándola, y no tendríamos un coeficiente de seguridad contra la trituración igual á 6 en la parte superior de la viga, hasta tanto que, como en el caso de los extremos, distribuyamos la carga en 117 cm de longitud ó en 80 cm para una seguridad de 4.

**La carga de seguridad** es en este caso $^1/_6$ de la de ruptura, y ésta es de 204 kg en el centro de una viga que tenga 25 mm de sección en cuadro y .30 m de luz. Para construcciones simplemente temporales puede agregarse 50 % á las cargas de la tabla, convirtiéndolas así en ¼ parte de la carga de ruptura. Pero en construcciones de importancia, sujetas á vibraciones, debe sustraerse 25 % á las cargas tubulares, reduciéndolas así á ⅛ de la carga de ruptura. Sobre todo si la madera no está bien seca.

**Con las cargas de seguridad de esta tabla una viga puede doblarse demasiado** para muchas aplicaciones prácticas. Cuando así sea, podemos, por la reducción de las cargas, reducir las flexiones casi en la misma proporción.

Todas las cargas de la tabla son cargas de **seguridad excesiva contra el esfuerzo cortante, contra la trituración en los extremos**, etc.; véanse las « Advertencias » que siguen á continuación de la tabla.

---

bezada .25 mm da los pesos que producen una mella de .25 mm. La segunda columna encabezada 2.5 mm da los que producen una mella de 2.5 mm.

★*N. del T.* — Este consejo no debe olvidarse, pues realmente esta tabla está hecha con maderas en muy buenas condiciones, porque las cargas comparadas con las de otras varias tablas son siempre mayores.

(*Obs. del T.* — Hemos convertido al sistema métrico la tabla **original** del autor. Como se dijo arriba, á las vigas en esta tabla se les supone 2.5 centímetros de ancho. Con esta tabla puede calcularse la carga para cualquier viga de ancho, altura ó luz distintas á las de la tabla si se recuerda que la resistencia varía en proporción del ancho, en proporción al cuadrado de la altura y en razón inversa de la luz. No sabemos con qué fórmula ni con cuáles experiencias formó el autor esta tabla; pero llamando B el ancho de la viga; D, su altura, y L, la luz, tomando las primeras en centímetros y la última en decímetros; calculando la resistencia segura de la madera á la tensión en 10 kg por cm cuad y empleando la fórmula muy conocida $\frac{RI}{T} = \frac{I}{n} Pl$; en que $\frac{I}{T} = \frac{BD^3}{6}$ (pág. 491, para vigas de sección rectangular); $n = 4$, para vigas apoyadas en los extremos y cargadas en el centro, y R = 10 kg, como ya dijimos, resultan para P valores muy aproximados á los de la tabla.)

**El roble blanco y el mejor pitchpine* del sur** soportarán cargas ¼ parte mayores.

**Para el hierro colado** multiplíquense las **cargas** de la tabla por 4.5, y para el **hierro forjado**, por 5.3. Para estas nuevas cargas multiplíquense las **flexiones** por .4 para el hierro colado, y por .3 para el forjado.

**Si la carga está uniformemente** distribuída sobre **la luz** puede ser el doble de la central, y las flexiones serán 1¼ veces las de la tabla. **Si las cargas de la tabla** están distribuídas uniformemente á lo largo de **toda** la viga, las flexiones no serán sino $^5/_4$ de las de la tabla. Cuando se requiera mayor exactitud, la mitad del peso propio de la viga debe sustraerse de la carga central; y todo él cuando la carga está uniformemente distribuída. El peso de la viga, en la última columna, está calculado suponiendo que la madera está regularmente seca y por tanto que pesa 461 kg por m cúb.

**Usos de la tabla anterior.** Ejemplo 1.° ¿Cuál deberá ser el ancho de una viga horizontal, rectangular, de pino blanco, que tiene 35 cm de altura, apoyada en ambos extremos y con 6 m de longitud entre sus apoyos, para que soporte con seguridad una carga de 5 toneladas (5,000 kg) en su centro? En este caso, frente á la altura de 35 cm de la tabla y en la columna de 6 m de abertura, encontramos que una viga con un espesor de 2.5 cm soporta 333 kg; por tanto $^{5000}/_{333} = 15$ cm, es el ancho buscado, porque la resistencia está en la misma proporción que el ancho.

Ejemplo 2.° ¿Cuál será la carga de seguridad en el centro de una viga para suelo ó durmiente de pino blanco, que tenga 5.40 m de largo, 7.5 cm de ancho y 30 de altura? En este caso, en la columna en cabeza da 5.40 m y frente á 30 cm de altura encontramos que la carga de seguridad para un ancho de 2.5 cm (supuesto en la tabla) es de 272 kg; por tanto $272 \times 3 = 816$ kg es la carga buscada.

*Nota.* **Advertencia en el uso de la tabla anterior.** Por ejemplo, al colocar cargas muy pesadas sobre vigas cortas pero altas y resistentes, debemos tener cuidado de que las vigas descansen en una longitud suficiente sobre sus soportes, de modo que se evite todo peligro de *ruptura* por trituración en los extremos. Así, si colocamos una carga de 2,756 kg en el centro de una viga que tenga de luz 1.20 m, de alto 45 cm y sólo 2½ de espesor, cada extremo de la viga soporta una fuerza de compresión vertical de $\frac{2{,}756}{2} = 1{,}378$ kg, que obra **transversalmente á las**

* *N. del T.* — Traduciremos á *pitchpine*, por *pichipen*, término muy usado en Sur-América.

**fibras.** En este caso, el pino blanco, el abeto y el pinabete se rompen por término medio bajo 56 kg por cm cuad, y para que presente una resistencia de seguridad de 6, es necesario que la presión se reduzca á cosa de 9.35 kg por cm cuad. Por tanto, nuestra viga, para que presente una resistencia de seguridad 6 contra la trituración (ruptura por compresión) de sus extremos, debe descansar en cada soporte en una superficie de $\frac{1,378}{9.35} = 147$ cm cuad ó para una carga seguridad de 4 como 98. Cuando una presión está igualmente distribuída en sentido transversal (esto es, perpendicularmente á la dirección de las fibras) sobre toda la superficie comprimida de un bloque ó viga (para lograr esto la superficie opuesta debe estar apoyada en todos sus puntos), la compresión que resulta puede escapar fácilmente á la observación, á menos que se la mida realmente. Pero cuando se aplica una presión considerable á una parte de la superficie, como en los topes ó pies de los postes, ó en los extremos de viguetas ó durmientes cargados, la compresión resalta á la vista porque las partes comprimidas se hunden más que las no oprimidas por causa de la flexión ó ruptura de las fibras adyacentes. Lo que en el primer caso (especialmente si es ligera) se llamaría **compresión**, sería llamada en el segundo caso **trituración**; aun cuando ninguna de ellas sea tan considerable como para hacerla insegura. Debido á la resistencia que dichas fibras adyacentes oponen á la flexión ó ruptura, es claro que una presión dada **por pulgada cuadrada, por cm cuad ó por pie cuadrado**, etc., causará una compresión ó trituración algo menor cuando se aplica á una sola parte de la superficie que cuando se la aplica á toda ella.

**El autor ha visto** 40 soportes de pinabete, medio secos, de 30 cm en cuadro cada uno, apoyados á intervalos de 1.52 m de centro á centro, sobre umbrales semejantes de pinabete de 30 × 30 cm, á los cuales estaban fijos por espigas, y que descansaban en todo su largo sobre peldaños de piedra. Cada poste fué cargado gradualmente con 32 toneladas ó 35.15 kg por cm cuad; y sus pies todos se introdujeron en los umbrales de 6 á 12 milímetros. Sus cabezas se introdujeron á la misma profundidad. **En la práctica**, la presión en las cabezas y bases de los postes, rara vez y quizás nunca, es uniforme; lo mismo sucede con los extremos de las viguetas y vigas cargadas, etc., en las cuales un ligero doblez causa un aumento de presión en los bordes inferiores de sus apoyos.

**Art. 31. Tabla de las mayores cargas centrales para vigas horizontales de pino blanco, amarillo ó abeto, de sección rectangular, y de 2½ cm de ancho, sostenidas en ambos extremos, y sin que presenten una flexión mayor de $^1/_{180}$ de la luz. En la práctica, por nudos, etc., tómense los $^2/_3$ solamente.**

Los pesos en esta tabla incluyen el peso de la viga en la luz : $^6/_4$ de este peso debe ser deducido de las cargas de la tabla, cuando la viga está cargada en el centro. Cuando lo esté uniformemente, las cargas serán 1.6 veces las de la tabla, pero en este caso se deducirá todo el peso de la viga. En la práctica rara vez se hace esta deducción.

Del lado acá de la linea gruesa las cargas de seguridad de la tabla pág. 1054 no llegarán á flexar las vigas de madera en 1/480 de su luz.

**Hierro y acero.** — Con el hierro colado, y para igual flexión, soportará 11 1/2 veces lo que soporta el pino blanco, el amarillo ó el abeto. El hierro forjado 19 veces. Como se ha dicho para la madera, debe deducirse la misma proporción del peso de la viga. El promedio para el acero es de 29 veces el del pino.

# COLUMNAS DE MADERA

(*Obs. del T.* — Algunas fórmulas y tablas, en que el autor trata esta materia, resultan, al convertirlas, poco prácticas para su uso en sistema métrico. Además, están muy recargadas de teorías. Las hemos reemplazado por 3 tablas muy prácticas tomadas del « Aide-Mémoire des Conducteurs des Ponts et Chaussées, etc. », por J. Eug. Petit, con su autorización.)

## Indicaciones generales.

Las únicas experiencias que se tienen sobre esta materia son experiencias de ruptura.

| Según las experiencias de Rondelet, tenemos : | Encina. | Pino. |
|---|---|---|
| Carga práctica por metro cuadrado..... | $.4\times10^5$ | $.4\times10^5$ |
| Carga de ruptura por metro cuadrado..... | $4.5\times10^5$ | $4.5\times10^5$ |

Para la resistencia al aplastamiento, Rondelet prescribe no dar á las piezas una longitud superior á diez veces el diámetro de la base y tomar como medida una carga de 50 kilos por centímetro cuadrado de la base.

Si el poste en lugar de ser redondo es rectangular, es necesario tomar la raíz cuadrada de la superficie de la base, para obtener el lado medio que debe servir de guía para la longitud. Rondelet agrega que la carga práctica permanente no debe pasar de $^1/_5$ de la carga de aplastamiento.

## Cargas prácticas de los postes de madera.

M. Hodgkinson ha dado también las fórmulas para calcular las cargas prácticas que se pueden hacer soportar á los postes de encina ó de pino.

Estas fórmulas son las siguientes :

1.° Postes cuadrados de encina :

$$P=256.5\times\frac{c^4}{l^2}\left\{\begin{array}{l}c=\text{lado del poste;}\\ l=\text{largo del poste.}\end{array}\right.$$

2.° Postes rectangulares de encina :

$$P=256.5\times\frac{ab^3}{l^2}\left\{\begin{array}{l}a=\text{lado pequeño del rectángulo;}\\ b=\text{lado grande del rectángulo;}\\ l=\text{largo del poste.}\end{array}\right.$$

3.° Postes cuadrados de pino :

$$P=180\times\frac{c^4}{l^2}.$$

4.° Postes rectangulares de pino :

$$P=180\times\frac{ab^3}{l^2}.$$

*Nota.* $a$, $b$, $c$, están expresadas en centímetros y $l$ en decímetros.

El número 180 es un término medio. Se pueden tomar 214 para el pino rojo y 160 para el pino poco resistente.

Estas fórmulas son aplicables desde $\frac{l}{c}=1$ hasta $\frac{l}{c}=35$.

*Problema* 1. ¿Qué peso se puede hacer sostener á un poste de sección cuadrada, de encina fuerte, de .22 m de lado y 2.50 m de altura?

La fórmula es :

$$P=256.5\times\frac{22^4}{25^2}$$
$$=256.5\times375$$
$$=96187\text{ kg.}$$

*Problema* 2. Determinar la escuadría de un poste de sección cuadrada, de encina fuerte, de 5 metros de alto y destinado á sostener una carga de 12,000 kilogramos.

La fórmula en tal caso es:

$$P = 256.5 \times \frac{c^4}{l^2},$$

en la cual:

$P = 2{,}000^k$, $l = 50$ decímetros.

Da:

$$c^4 = \frac{12{,}000^k \times 50^2}{265.5} = 116{,}960;$$ de donde $c = .185$ m.

## Tabla que da las cargas prácticas de los postes de madera de sección cuadrada para alturas de 2 á 10 metros.

(Tomadas del tratado de carpintería del Sr. Oslet.)

| 30 | » | » | » | » | « | 18700 | 16000 | 14000 | 12000 |

*Nota.* Esta tabla da la carga práctica que pueden sostener, con entera seguridad, os postes de encina y pino flojos, de 2 metros á 10 metros y escuadrías de .10 m á .30 m cuadrados. Se han adoptado 40 kilogramos por centímetro cuadrado para carga práctica.

Esta tabla debe emplearse para construcciones que no necesiten maderas de primera calidad.

## Tabla n.º 2.

| Lado del cuadrado en cm. | Alto de los postes (encina fuerte, 60 kg por cm cuadrado). | | | | | | | | |

*Nota.* Los elementos de esta tabla deberán emplearse para maderas de pino d muy buena calidad pudiendo resistir 50 kilogramos por centímetro cuadrado

## Aplicación de las tablas anteriores.

*Problema* 1. Hallar las dimensiones de un poste de madera de encina floja que pueda sostener una carga de 5,000 kg, teniendo una altura de 4 metros.

Se busca en la columna 4 *metros*, de la tabla n.º 1, el número 5,000 kg y hallamos que esta cifra corresponde á una escuadría de .16/.16.

*Problema* 2. ¿Cuál es el peso que puede soportar un poste cuadrado de encina fuerte de .18/.18, teniendo una longitud de 6 metros?

Se busca en la primera columna de la tabla n.º 2 el número 18 y se sigue la línea horizontal hasta la columna 6 m. Hallamos que el peso que corresponde es de 6,400 kg.

*Primera observación.* Si el poste es rectangular, se busca primero la carga de un poste cuadrado cuya escuadría será el lado más pequeño de la sección, y en seguida se multiplica el resultado por la relación de las dos dimensiones de la sección transversal. Ejemplo. Supongamos un poste de encina floja de 4 metros de altura, cuya escuadría es 20/25.

Se busca la carga de un poste cuadrado de 20/20 y de 4 metros y hallamos 9,500 kg. Se multiplica en seguida 9,500 kg por la proporción 25 : 20 = 1.25.

$$9{,}500 \times 1.25 = 11{,}875 \text{ kg.}$$

Este resultado nos da la carga que puede sostener un poste rectangularde 20/25 teniendo 4 metros de altura.

*Segunda observación.* Si tenemos un poste superior á .30/.30, cuya escuadría no se encuentra en las tablas, se procede entonces de la manera siguiente:

Supongamos un poste de .36/.36 y de 8 metros de altura, de encina floja. Si reducimos á la mitad las dimensiones del poste (altura y lado de su sección transversal), la carga total queda reducida á la cuarta parte. Se trata pues, en este caso, de buscar la resistencia de un poste cuadrado de .18 de lado y de 4 metros de altura, lo que, según la tabla n.º 1, da 7,000 kg.

Por consiguiente, la carga correspondiente al poste de 8 metros de altura y de $.36 \times .36$ es el cuádrupie de la anterior. Así pues: $7{,}000 \times 4 = 28{,}000$ kg.

## REQUISITOS PARA EL HIERRO Y EL ACERO

(Véase también en Especificaciones para puentes.)

**Resumen de especificaciones** adoptadas, con sujeción á votación por letras en la 4.ª Reunión Anual de la **Sección Americana** de la **Asociación internacional para ensayo de materiales**, el 29 de junio de 1901. Adoptadas por votación por letras, en agosto de 1901, excepto para el hierro forjado, respecto del cual se difirió la decisión.

### Proceso de manufactura.

Hierro forjado; pudelado, ó laminado de pilas de recortes de hierro forjado, solo ó agregándoles hierro de primera laminación. Fundiciones de acero. Procedimiento Martín Siemens, de crisol ó de Bessemer.

Forjaduras de acero. Procedimiento Martín Siemens, de crisol ó de Bessemer.

Carriles de acero. Bessemer ó Martín Siemens.

Los lingotes se tendrán verticales en hornos de pozo. No se usarán lingotes sangrados. Se descartará suficiente material de los topes de los lingotes para asegurar la solidez de los carriles.

Barras de unión de acero. Bessemer ó Martín Siemens.

Planchas de caldera y acero de remache. Martín Siemens.

Acero de construcción para puentes y buques. Martín Siemens.

Acero de construcción para edificios. Martín Siemens ó Bessemer.

### Piezas de prueba.

Para planchas chatas se usará la muestra expuesta en la fig. J.

*La pieza ha de ser del mismo espesor que la plancha.*

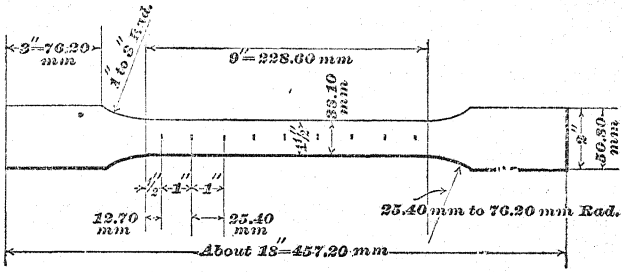

**Fig. J.**

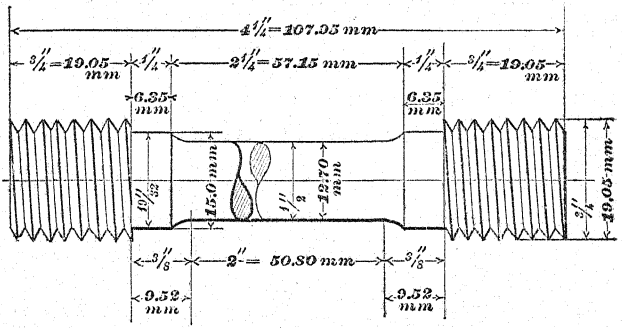

**Fig. K.**

Para grandes baquetas, muestra de prueba señalada en la fig. K. El centro de la muestra estará á media distancia entre el centro y el exterior de la baqueta.

Siempre que sea posible, el hierro se probará en tamaño entero, como se laminó.

Las muestras de prueba se cortarán de la barra como se hayan laminado.

## Pruebas.

**Pruebas de tarja.** La muestra será ligera y uniformemente tarjada de un lado y doblada hacia atrás en este punto hasta un ángulo de 180° dándole una serie de golpes ligeros.

**Pruebas de flexión al fuego.** Las piezas de prueba serán calentadas á un rojo brillante y dobladas por presión y por una sucesión de golpes ligeros, sin martillar en la cabeza.

**Pruebas de flexión al frío.** Las muestras deberán doblarse por presión ó por sucesivos golpes ligeros.

**El punto donde empieza á ceder** (*yield point*) será determinado por cuidadosa observación de la caída del balancín ó por el escantillón de la máquina de pruebas.

**Pruebas de precisión.** Esta máquina para probar carriles tendrá una maza de 2,000 libras (906 kg), cuya superficie golpeante tendrá un radio de no más de 5 pulgadas (12.7 cm); y el carril de prueba, de no más de 6 pies (1.83 m) de largo, se colocará con la cabeza hacia arriba sobre sólidos apoyos distantes 3 pies (.91 m). La masa del yunque, que debe pesar por lo menos 20,000 lbs (9,060 kg), y los apoyos formarán parte del yunque ó estarán firmemente ligados á él. La caída de la masa de 4.57 m para carril de 22.5 kg por m á 5.79 m para carril de 42.5 kg ó más. De cada quinta hornada se escoge una pieza de prueba.

**Pruebas de homogeneidad para acero de las cajas de fuego.** Una parte de la muestra rota en la prueba de tensión, se tarja ó se estría á $^1/_{16}$ de pulg (1½ mm) de profundidad en tres lugares distantes como 2 pulgs (5 cm) y en lados opuestos. Entonces se sujeta en un torno y se rompe con ligeros golpes de martillo, doblándola sucesivamente por cada estría. La muestra no debe presentar ni una sola rasgadura ó cavidad de más de $^1/_4$ de pulg (6 mm) de largo.

## Notas al cuadro que sigue.

(*a*) Enteramente doblado.

(*b*) La muestra ha de doblarse sobre una barra de diámetro igual á su propio diámetro ó espesor.

(*c*) La muestra ha de doblarse sobre una barra de dos veces su diámetro.

(*d*) Alargamiento mín por ciento, en secciones menores de .654 lbs, por pie lineal (.97 kg por metro), clase A, 19; B, 15; C, 12.

(*e*) Prueba de tarja. Máx por ciento de superficie granular, clase A, 10; B, 10; C, 15.

(*f*) Prueba de flexión al fuego. La barra ha de doblarse sin rasgarse en la parte exterior del doblez. Cada clase debe doblarse: 180° en las clases A y B y rigurosamente á 90° en C. La clase A al calor amarillo y súbitamente apagado en agua, entre 80 y 90° F. (26.7 y 32.2 C) debe doblarse á 180°. También, calentado al rojo brillante rasgado en el extremo y doblada cada parte hacia atrás á 180°. Punzado para taladrar lo menos .9 del diámetro ó ancho de la barra.

(*g*) Fósforo, piezas para prueba física, .05 para cada clase.

(*h*) Azufre, piezas para prueba física, .05 para cada clase.

(*i*) Flexión. Muestra una pulgada × ½ pulg (25 × 13 mm) ha de doblarse en frío sobre una barra de 1 pulgada de diámetro (25 mm) sin fractura en el exterior del doblez.

(*j*) Flexión. Muestra 1 pulgada × ½ pulgada (25 × 13 mm) para doblarse en frío, sin fractura en el exterior del doblez sobre una barra de ½ pulgada (12½ mm).

(*k*) Lo mismo, alrededor de un diámetro de 1½ pulgs (38 mm).

(*l*) Lo mismo, alrededor de un diámetro de 1½ pulgs (38 mm), si no tiene menos de 20 pulgs (51 cm) de diámetro, alrededor de un diámetro de 1 pulg (25 mm), si tiene menos de 20 pulgs (51 cm) de diám.

(*m*) Lo mismo, sobre un diámetro de 1 pulgada (25 mm).

(*n*) Lo mismo, sobre un diámetro de ½ pulg (12½ mm).

(*o*) Lo mismo, sobre un diámetro de 1 pulg (25 mm).

(*p*) Dedúzcase 1 por ciento por cada $^1/_4$ pulg (3 mm) en espesores mayores de

$^{3}/_{4}$ de pulg (19 mm), y 2½ por ciento por cada $^{1}/_{16}$ de pulg (1½ mm) en menos de $^{5}/_{16}$ de pulg (8 mm).

(*q*) Flexión. Las barras para hacer remaches han de probarse enteras, como salen del laminador. Las muestras de las planchas serán de 1½ pulg (38 mm) de ancho. Las planchas de no más de $^{3}/_{4}$ de pulg (19 mm) de espesor, tendrán el mismo ancho que la plancha y la muestra tendrá, cuando sea posible, la superficie laminada en ambas caras. Para planchas más gruesas de $^{3}/_{4}$ de pulg (19 mm), la muestra podrá ser de ½ pulg (12½ mm). Serán sometidas á las pruebas de flexión en frío y apagada. Para apagar, el material ha de calentarse al rojo cerezo claro (visto en la obscuridad) y apagarse en agua á temperatura, entre 80° y 90° Fahr (26.7 y 32.2 C). Las muestras deberán doblarse sin fractura en el exterior. La flexión puede hacerse por presión ó por golpes.

(*r*) Para pasadores, el alargamiento será de 5 por ciento menos. El centro de la muestra de prueba á 1 pulg (25 mm) de la superficie.

(*s*) Las barras de ojo serán de acero mediano. Pruebas de tamaño entero darán 12½ por ciento de alargamiento en 15 pies (4.57 m). Tensión mín, 55,000 lbs por pulg cuad (3,850 kg por cm cuad). Por lo menos $^{2}/_{3}$ de las barras de ojo probadas se romperán en el cuerpo de la pieza.

(*t*) Lo mismo que (*q*), pero omitiendo la prueba de la apagada.

(*u*) Véase Prueba de homogeneidad, en el texto, arriba.

Véanse notas, p. 1194 y 1195.

**Resumen de especificaciones que sirven de norma á los manufactureros del acero**, adoptadas por la Asociación Americana de Manufactureros de Acero el 9 de agosto de 1895 y revisadas el 6 de febrero de 1901. En vigencia el 31 de julio de 1908.

Las **palabras entre paréntesis** en tipo grueso (como **puede ser Martín Siemens ó Bessemer**) se aplican sólo á acero de construcción. Las palabras entre paréntesis *en bastardilla* como (*cuatro*), (*dos*) se sustituirán con las palabras precedentes (**dos**), (*uno*), para acero especial Martín Siemens de plancha y remaches. De otro modo, y sólo cuando se diga especialmente, las indicacions se aplicarán á ambos aceros.

---

(Pueden ser **Martín Siemens ó Besseimer.**)

Las **pruebas é inspecciones** se harán en el lugar de la manufactura antes del embarque.

### Piezas de prueba.

**Piezas de prueba modelo para planchas cizalladas.** (Véase fig. J, pág. 1193.)

**Piezas de prueba de otro material**, ya como se dice arriba, ya acepilladas ó torneadas paralelas á la longitud de la pieza.

En todo caso, los lados opuestos de la pieza de prueba han de ser laminados, si fuese posible.

« **Barretas y barras para remaches** deben probarse en su longitud completa como salen del laminador. »

« **Dos** (*cuatro*) **piezas de prueba** se tomarán de cada fundición (ú hornada) de material acabado, una (*dos*) para tensión y una (*dos*) para flexión; pero en caso de que en cualquier prueba se encuentren defectos, ó que la pieza de prueba de tensión se rompa fuera del tercio medio de su longitud, podrá desecharse y sustituirse por otra. »

« Cuando un material haya de ser **templado ó tratado de otro modo** antes de emplearse, su muestra será tratada del mismo modo antes de probarla. » Es decir, el material « será probado en la condición en que salga de los cilindros ».

« En toda pieza de acero será **estampado** el número de fundición (ó de hornada), y el acero para pasadores llevará dicho número estampado en los extremos. El acero para remaches (y las piezas pequeñas para planchas de pasadores y refuerzos pueden embarcarse en haces bien atados con alambre, con el número de la hornada ó de la fundición en una placa atada de metal. »

### Máximum de fósforo y azufre por ciento.

| Be construcción | Fósforo. | Azufre. |
|---|---|---|
| para edificios, tinglados, puentes de camino real, etc..... | .10 | ... |
| para puentes de ferrocarril..... | .08 | ... |
| Especial | | |
| acero de calderas..... | .06 | .04 |
| acero extradulce y para cajas de fuego..... | .04 | .04 |

### Propiedades mecánicas.

| | Acero de construcción. | | | Acero especial. | | |
|---|---|---|---|---|---|---|
| | Remache. | Puentes de ferrocarril. | Mediano. | Extradulce *. | Caja de fuego. | Para caldera. |
| Prueba de flexión § 180° sin fractura en el exterior del doblez..... | 0 | t | t | 0** | 0** | 0** |
| Máxima resistencia á la tensión en miles de kgs por cm. cuad..... | 3.36 á 4.06 | 3.85 á 4.55 | 4.2 á 4.9 | 3.15 á 3.85 | 3.64 á 4.34 | 3.85 á 4.55 |
| Alargamiento (para deducciones, etc., véase abajo)..... | 98,434 ÷ Máx resistencia. | | | | | |
| Límite de elasticidad..... | No menos de la mitad del máximo de resistencia. | | | | | |

* Los remaches de caldera han de ser de acero « extradulce ».

** Flexión en frío ó apagada.

= espesor de la pieza de prueba.

**El alargamiento**, en barras de $^5/_8$ pulg (16 mm), ó menos, medidas en una longitud = 8 × diám de sección probada; en otros casos, medidas en 8 pulgs (20.3 cm). De los alargamientos especificados, han de hacerse las siguientes **deducciones: *por cada* aumento** de espesor de $^1/_8$ pulg (3 mm) **en más de $^3/_4$ pulg** (19 mm) 1%; (mín 20% para material de barras de ojo, 18% para otra material de construcción); para **cada disminución** de $^1/_{16}$ pulg (1½ mm) en menos de $^5/_{16}$ pulg (8 mm), 2.5%; para pasadores, 5%; el alargamiento debe medirse « en una pieza de prueba, cuyo centro esté á una pulg (25 mm) de la superficie de la barra ».

**Percentaje de variación permitida en peso ó sección transversal de planchas cizalladas.**

**Cuando se ordenan por peso.**

| Peso por m cad. | | < 61 kg | | < 61 kg | |
|---|---|---|---|---|---|
| | cm. | cm. | cm. | cm. | cm. |
| Ancho en cm... | < 190.5 | 190.5 á 254 | < 256 | < 254 | < 254 |
| Variación %.... | ± 2.5 | + 5, — 3 | + 10, — 3 | ± 2.5 | ± 5 |

**Cuando se ordenan por escantillón**, percentaje de exceso en planchas rectangulares. (Planchas con > .01 pulgada (.25 mm) en menos se consideran dentro del escantillón.) Al acero laminado se le supone una densidad de 7.82.

| Espesor en milímetros. | Ancho en cm. <127 | á 177.8 | > 177.8 | < 190.5 á 254 | 254 á 292.1 | 292.1 |
|---|---|---|---|---|---|---|
| 3.175 á 3.9687 | 25.40 | 38.10 | 50.8 | | | |
| 3.9687 á 4.762 | 21.59 | 31.75 | 43.18 | | | |
| 4.762 á 6.350 | 17.78 | 25.40 | 38.10 | | | |
| 6.350 | ..... | | | 25.4 | 35.56 | 45.72 |
| 7.937 | ..... | | | 20.32 | 30.48 | 40.64 |
| 9.525 | ..... | | | 17.78 | 25.40 | 33.02 | 43.18 |
| 11.112 | ..... | | | 15.24 | 20.32 | 25.40 | 33.02 |
| 12.700 | ..... | | | 12.70 | 17.78 | 22.86 | 30.48 |
| 14.287 | ..... | | | 11.43 | 16.51 | 21.59 | 27.94 |
| 15.875 | ..... | | | 10.16 | 15.24 | 20.32 | 25.40 |
| > 15.875 | ..... | | | 8.89 | 12.70 | 16.51 | 22.86 |

En otros casos, una variación > 2.5% en peso ó sección transversal será motivo suficiente de rechazo.

**El frío intenso debilita el hierro.**

La creencia (que tuvo origen en Styff, de Suecia) va ganando terreno. Se cree que el hierro y el acero no se hacen *más quebradizos por el frío intenso*, sino que, el gran número de rupturas de carriles, ruedas, ejes, etc., en el invierno, se debe al mayor efecto de los golpes por causa de la helada y falta de elasticidad de la tierra en aquella estación del año. Pero los experimentos de Sandberg demuestran terminantemente que, aunque estos metales pueden tal vez resistir en invierno como en verano la misma fuerza *gradualmente* aplicada, su resistencia á los golpes ó *fuerza súbita*, no es más de ½ ó ⅓ en el frío riguroso; porque éste los hace menos flexibles y menos dilatables. Es probable que no se atienda á esta circunstancia con todo el interés que merece al calcular puentes de hierro, etc.

Algunos experimentos con buen hierro forjado han demostrado que aun á 23° F (—5° C) ó tan sólo 9° F (5° C) debajo del punto de congelación, se produce una pérdida de resistencia de 2½ á 4 por ciento.

**Hierro fundido maleable.** Los experimentos de D. L. Barnes, de Chicago, en gran número de muestras de una misma fábrica de hierro fundido « maleable », dieron en la mayor parte de los casos tensiones que variaron de 24,000 á 32,000 lbs por pulg cuadrada (1,680 á 2,240 kg por cm cuad) con un promedio de 28,000 (1,960). Las cifras más altas fueron obtenidas generalmente con las barras más pequeñas (como de 3 × ¼ pulg (7½ × .6 cm), y las más bajas con las barras más gruesas (como de 3 × 1 pulg (7½ × 2.5 cm). Piezas acepilladas en los cuatro lados dieron sólo un promedio de 24,000 lbs por pulg cuad (1,680 kg por cm cuad). Esto puede

explicar la diferencia en favor de las secciones más pequeñas, en las cuales la cubierta original forma una gran parte de la sección transversal.

## HIERRO FUNDIDO

**El galvanismo es simplemente una capa delgada de cinc en** ambos lados de la plancha; como lo que se conoce por «hojalata» ó planchas estañadas, que son en realidad hierro en planchas cubierto con estaño. El cinc así como el estaño resiste á la corrosión por la influencia atmosférica ordinaria mucho más que el hierro, y de aquí el uso de estos metales para proteger el hierro. Un techo de buen declive, bien galvanizado, sólo sufrirá un poco, en 5 ó 6 años, sin haber sido reparado. Coge fácilmente la pintura y debe pintarse de vez en cuando. Es mejor, sin embargo, pintarlos de una vez con estaño.

**La pintura no se adhiere bien al cinc nuevo** y esta es la razón principal por la cual no se pintan los techos nuevos galvanizados; pero esto puede remediarse dándole una mano al cinc con la siguiente preparación: disuélvase 1 parte de cloruro de cobre, 1 parte de nitrato de cobre y otra de sal amoníaco, en 64 partes de agua; agréguese entonces 1 parte de ácido clorhídrico del comercio. Cuando se le da la mano con esta solución, se pone negro el cinc. Séquese de 12 á 24 horas y después puede pintarse.

Se emplea generalmente la pintura con óxidos minerales de color castaño y le aplican una mano en ambos lados en el taller y la otra después de haber sido colocado en el techo. Bastará después pintarlos de nuevo cada 3 ó 4 años. El hierro no galvanizado (llamado hierro negro, por distinción), es también muy resistente para techos, si se pinta bien cada 1 ó 2 años. La ventaja principal del techo galvanizado es que no necesita ser pintado tan á menudo como el de hierro negro. El galvanismo aumenta como .8 kg por metro cuadrado de superficie cubierta ó como 1.60 kg por m cuadrado de plancha, por ambos lados, sin tomar en cuenta el grueso de la plancha. La pintura para techos no debe contener mucho secante. Véase el capítulo Pintura.

Los humos sulfurosos del carbón corroen mucho el hierro galvanizado y el negro: como puede verse en los talleres, puentes de ferrocarril ó edificios para máquinas techados con uno de los dos, y cuando no se emplean medios eficaces para alejar el humo. Lo mismo sucede con otros metales. Se dice que el ácido del roble destruye el cinc del hierro galvanizado. Véase el capítulo titulado Estaño y Cinc más adelante. El hierro en planchas se clava generalmente sobre tablas próximas; pero la resistencia del hierro acanalado evita la necesidad de esto y permite que se coloquen planchas separadas de 1.50 á 1.80 metros de viga á viga sin sostén intermedio. Las planchas de hierro acanalado se fijan al techo por medio de remaches de alambre galvanizado como de 3 mm de grueso de á 660 en kg (y bien clavados á fin de impedir que pase el agua de lluvia) con ocho ó diez cms de distancia en todo el rededor. Los agujeros de los remaches se hacen de antemano por medio de taladros á fin de asegurarse de la coincidencia de las diferentes planchas. Los remaches son clavados por dos hombres, uno por arriba y otro por debajo del techo. Para el hierro negro y para techar con tablitas delgadas ó empizarrar, se usan comúnmente, como un preservativo parcial contra la corrosión, los clavos sin galvanizar, hervidos en aceite de linaza. Los clavos galvanizados son sin embargo mejores en todos estos casos y aun los de cobre para empizarrar, porque una buena pizarra dura mucho más tiempo que la tabla y el hierro y viene á ser, por tanto, una verdadera economía el usar metales durables para clavarlos. En ninguno de estos casos están los clavos expuestos completamente á la intemperie.

**Las planchas de hierro planas** se colocan doblando las orillas más ó menos como lo demuestra la figura, pág. 1251.

Las juntas en el sentido de la corriente se hacen como en *ss*, y las horizontales como en *tt;* excepto que, como quiera que éstas no están soldadas en las planchas de hierro, la junta está hecha como de ¾ á 1 pulgada (19 á 25 mm) de ancho en lugar de ¼ de pulgada (6 mm) que es lo mejor para evitar filtraciones. Se usan

lañas como en el estaño, con dos clavos para cada laña. Las planchas de hierro se colocan mejor sobre entarimado de tablas; pero en los tinglados, etc., se colocan algunas veces directamente sobre los pares, separadas no más de 18 pulgadas (45 cm) dejando que las planchas sobresalgan un poco de las vigas á fin de formar ramblas que den salida al agua. En semejantes casos será bueno disponer los extremos superiores de los pares como en esta figura.

**Una seria objeción sobre el hierro como cubierta de un techo** es la rápida condensación de la humedad atmosférica : que cae del hierro en gotas, en forma de lluvia y puede ser perjudicial á los cielos rasos, pisos, ó á los efectos que están en los departamentos debajo del techo. La pintura no disminuye apreciablemente este efecto; puede evitarse sin embargo enyesando.

**Planchas de hierro acanalado.** El tamaño ordinario de las planchas acanaladas es de 30 pulgadas de ancho por 96 de largo (.76 m × 2.44 m). El acanalado reduce la anchura á 27½ pulgadas (.70 m). Cuando las planchas acanaladas se colocan sobre el techo, la superposición de 6 cm en todo el largo de los lados y 10 cm en sus extremos disminuye el área cubierta de techo por una plancha como á siete octavos de la superficie de la plancha entera acanalada; y el peso por metro cuadrado de techo cubierto es como una séptima parte mayor que el de la plancha acanalada por metro cuadrado. El peso de hierro acanalado por metro cuadrado de techo cubierto es como una quinta parte mayor que el de las planchas planas con que se hacen las acanaladas.

Se calcula generalmente como en 15 cm el vuelo de los aleros.

Los pesos por pies cuadrados correspondientes á los diferentes números del calibrador Birmingham varían un tanto entre los diferentes fabricantes. Los dos sistemas de acanalado, dados en la tabla que sigue, 5 × 1¼ y 2½ × ⅛, son los más frecuentemente usados.

| N.º del calibrador Birmingham. | Espesor en pulgs. | Peso en libras por pie cuadrado de planchas. | | Peso en libras por pie cuadrado de techo. | |

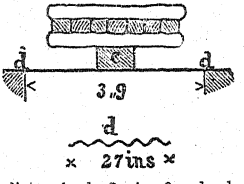
## Resistencia del hierro acanalado. Experimentos del autor.

**Primero. Una plancha de hierro** *dd* **n.º 16** (como de $^1/_{17}$ de pulgada (1.69 mm) de grueso) 27 pulgadas de ancho (.686 m), por 4 pies (1.219 m) de largo, con 5 canales completos de 5 pulgadas por 1 pulgada (.127 m × .025 m), fué



colocada sobre apoyos á distancia de 3 pies 9 pulgadas (1.14 m). Un trozo de madera *c* de 9 pulgadas de ancho por 7 pulgadas de espesor y 30 pulgadas de largo (.23 m × .18 m × .76 m), se colocó en el centro y se cargó gradualmente con hierros que pesaban 1,600 lbs (725.75 kg).

Esto produjo una flexión en el centro precisamente de ½ pulgada (13 mm). Al remover el peso después de una hora, no era apreciable ningún descenso permanente. La prueba se ratificó de propósito, aplicando los pesos de una manera brusca y sacudiéndolo todo lo más posible *. El área suspendida de la plancha era de 8.44 pies cuadrados (.78 metro cuadrado), y como la carga actual del centro de (725.75 kg) equivale como á 1,361 kg, *igualmente distribuídos*, tenemos 1,361 = $\frac{1,361}{.78}$ = 1,745 kg por metro cuadrado; pero 1,361 kg igualmente distribuídos sólo producirían una flexión como de 6 mm. Además, 1,745 kg por metro cuadrado es como 4 veces el peso de la mayor carga que se puede acumular sobre un piso.

Por consiguiente, esta plancha á 3'9" (1.14 m) de luz resiste prácticamente cualquiera sobrecarga ordinaria. Sin embargo, dicha sobrecarga producirá una flexión central de sólo ¼ parte de ¼ de pulgada, ó $^1/_{16}$ de una pulgada (1.59 mm), ó $^1/_{720}$ de toda la luz, lo cual es sólo las ⅔ partes del límite de Tredgold de $^1/_{480}$ de la abertura.

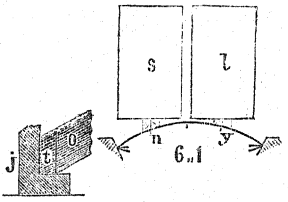
En uno de los experimentos los extremos de la plancha descansaban sobre apoyos preparados, de modo que presentan ondulaciones correspondientes muy próximamente á la forma del acanalado; pero en el otro los apoyos eran planos y cada extremo de la plancha descansaba solamente sobre los puntos inferiores del acanalado. No se observó ninguna diferencia apreciable en los resultados.

**Segundo. Una bóveda de hierro acanalado n. 18** ($^1/_{20}$ de pulgada (1.27 mm)) como el anterior; pero, aumentando la profundidad del acanalado á 1 ¼ pulgada (32 mm) por el procedimiento de arquear la plancha; con luz de 6 pies 1 pulg (1.85 m); elevación, 10 pulgadas (.25 m); ancho, 27 pulgadas

* Sin permitir que la flexión excediera de $^1/_2$ pulgada (12 mm), lo cual se impidió por medio de un apoyo colocado debajo de la plancha.

(.68 m) (de las cuales, sin embargo, sólo 25 pulgadas (.63 m) descansaban sobre los estribos).

Cada pie derecho *o* de la bóveda descansaba sobre una fundición *j*, cuya parte interior *t* estaba undulada en la parte superior, para corresponder á los acanalamientos del arco que descansaba sobre ella. En *y* (cuarta parte de la abertura) se colocaron dos trozos de madera que ocupaban una extensión de .23 m y que se prolongaban á lo largo de la bóveda; sobre ellos se acumuló una carga, *l*, de fundición de 4,480 libras ó 2 toneladas. Bajo esta carga, la bóveda, descendió como 12½ mm en *y* aplanándose en ese lado y formando una curva hacia arriba en



el lado sin carga *n*. Dos bloques parecidos fueron colocados entonces en *n* y sobre ellos 2 toneladas de carga *s* además de las 2 toneladas de *l*. formando un total de 4 toneladas. Esto llevó á la bóveda casi á su forma anterior, pero ligeramente aplanada en *n* é *y;* y un poco más curva en el centro. Entonces se aumentó la carga á 4,536 kg y se la dejó por algunos días. Se encontró que dos tirantes de hierro, cada uno de 12×42 mm, usados para impedir que los estribos se abrieran, se habían estirado cerca de 6 mm. Se añadieron otras cargas y se aumentó el peso á un total de 6 toneladas, parte de él en *s* y *l*, y parte en forma de largas y anchas barras de hierro en el centro del arco debajo de las cargas *s* y *l* y entre *n* é *y*. Según lo que se puede juzgar á la simple vista, la forma de la bóveda era casi perfecta. *Las cargas s* y *l no se tocaban*. Después de haber permanecido allí por más de una semana, la carga fué volteada accidentalmente deformando la bóveda. La carga era como de 4,882 kg por metro cuadrado de bóveda. Dichas bóvedas son desde entonces de uso común **para pisos contra el fuego** en lugar de las de ladrillo.

**Los techos curvos de 7 á 11 metros de abertura** y con una elevación como de ¼ de dicha abertura, pueden hacerse de hierro acanalado ordinario de los n.° 16 al 13, remachados como de costumbre y sin otros accesorios que tirantes de hierro á pocos metros de distancia y ángulos de hierro en los arranques, y pendolones de hierro para impedir que los tirantes se doblen.

**Tubos soldados de hierro forjado,** para vapor, gas y agua, con longitudes como de 18 pies (5.491 m).

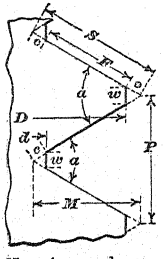
## Roscas de tornillo, pernos, tuercas y arandelas.

**Rosca de tornillo.** $a$=ángulo entre dos lados de una rosca; P=*paso* del tornillo; $w$=ancho del tope ó base plana de cada rosca; todo medido en un plano que



contenga el eje del tornillo; N=número de roscas por pulgada (25.4 mm)= 25.4 mm ÷ P. En los modelos Sellers, ó del Instituto Franklin, propuestos por

Mr. William Sellers y adoptados por el Instituto en 1864, $a=60°$; $S=P$; $w=c=P/S$; $F=.75\,P$; $M=P\cos a/2=.8660\,P$; D (diámetro) $=d+2\times.866\times.75P=d+1.299P$. Bajo el título de **Modelos de los Estados Unidos**, el Departamento de Marina adoptó en 1868 el sistema de Sellers, excepto para las cabezas y tuercas bien acabadas, las cuales hizo que fuesen iguales á las cabezas y tuercas bastas *.

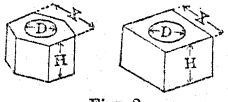
| X | 1½ D+3 mm | 1½D+1½ mm |
| H (en la cabeza) | ½ X | D—1½ mm |
| H (en la tuerca) | D | — — |



Figs. 2.

En la rosca del modelo **Whitworth** (inglés), el ángulo $a$, fig. 1, es de 55°. Los topes y bases de las roscas están redondeados, en vez de ser planos como en los modelos americanos. El número (N) de roscas por pulgada (por 25.4 mm) es el mismo que el anterior para diámetros de pernos hasta de tres pulgadas (76 mm), excepto para D= ½ pulgada (12½ mm) en que N=12.

En la **rosca métrica internacional**, adoptada en Zurich, en octubre de 1898, se hizo uso del perfil de la rosca de Sellers. Sus dimensiones son como sigue (en milímetros):

| Diám. | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 14 | 16 | 18 | 20 | 22 | 24 | 27 | 30 | 33 | 36 | 39 | 42 | 45 | 48 | 52 | 56 | 60 | 64 | 68 | 72 | 76 | 80 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Separación entre roscas. | 1.0 | | 1.25 | | 1.5 | | 1.75 | | 2.0 | | 2.5 | | 3.0 | | 3.5 | | 4.0 | | 4.5 | | 5.0 | | 5.5 | | 6.0 | | 6.5 | | 7.0 |

Los diámetros intermedios deben ser de un número completo de milímetros, y á la misma separación que el próximo diámetro menor de la tabla. Así, para diám de 65 ó 69 mm, la separación=6.0 mm.

* *N. del T.* — Hemos convertido estas tablas del autor á las equivalentes en medidas métricas.

Con las anteriores dimensiones un perno falla generalmente por quebradura entre la cabeza y la tuerca, donde el diámetro se ha disminuído en el corte de la rosca. **El diámetro D de la rosca** debe, naturalmente, ser mayor que el que se necesitá para soportar con seguridad la tensión que se desea, en una cantidad igual al *doble* del espesor de la rosca. El desperdicio de hierro que resulta al hacer *todo el perno* de aquel diámetro mayor, se evita haciendo el perno de una barra que tenga tan sólo las dimensiones necesarias para soportar el esfuerzo con seguridad, **y haciendo sus extremos más gruesos**, como se ve en la fig. 3 donde está aumentado su diámetro lo suficiente para el corte de la rosca.

En la carpintería así como en las traviesas para mamposterías, se colocan *arandelas ww* de hierro colado ó fundido entre la madera ó piedra y la tuerca y cabeza, á fin de distribuir la presión en una superficie mayor é impedir que se maltrate la superficie de contacto especialmente en la madera.

**Cuando hay mucha presión contra la madera**, el lado de una arandela cuadrada de hierro fundido, ó el diámetro *ww* de una circular no debe ser menos de 4 veces el diámetro del *tornillo* (como en la figura), y su espesor *tw* ½ diámetro por lo menos.

Dos arandelas cuadradas como éstas pesarán juntas como una longitud de 1.8 diámetros de una barra redonda del mismo diámetro que el tornillo. En cualquiera de los dos casos una tuerca y la cabeza cuadradas pesarán como 6 diámetros. Siendo as arandelas de hierro colado más propensas á romperse bajo presiones fuertes, deben hacerse dos veces más gruesas que las de hierro forjado. Cuando el esfuerzo es muy grande, el diámetro de la arandela debe ser 5 ó 6 veces el del tornillo, y su espesor igual al diámetro; pero 4 diámetros bastarán en la mayor parte de los casos, ó aun 2.5 cuando el esfuerzo es pequeño; el grueso puede ser entonces de .14 .2 del diámetro del tornillo.

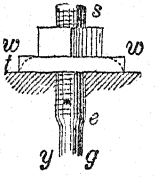


Fig. 3.

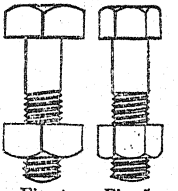

Fig. 4. Fig. 5.

**Tabla de tornillos ó pernos de máquinas y de carros**, cabeza y tuerca cuadradas y hexagonales, figs. 4 y 5, hechas por Hoopes y Townsend, Filadelfia. Todos sus tornillos son hechos de filetes **modelo de los Estados Unidos**, según la tabla pág. 1209, á menos que expresamente sean pedidos de otra forma.

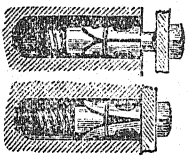
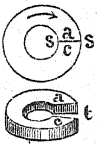
**Pernos de expansión**, para fijar planchas, maderas, etc., á muros de ladrillos ó mampostería ordinaria. La tuerca cuneiforme que corre hacia arriba del perno, á proporción que éste da vuelta, comprime las alas contra los lados del hueco, el cual en la práctica se perfora con ancho suficiente para admitir la tuerca y las alas,

y para impedir que gire la tuerca junto con el perno. Si se hace el hueco más grande, como se ve, la tuerca debe sujetarse por medio de una pequeña cuña.





**Arandelas para tuercas de seguridad** (*lock-nut*). Cuando los pernos están sujetos á movimientos bruscos como en las bridas de los carriles, etc., las tuercas están *expuestas á aflojarse y á destornillarse por sí mismas*. En los ferrocarriles este es motivo de grandes inconvenientes y se han empleado multitud de invenciones para impedirlo. La tuerca de seguridad **Verona** es una simple arandela circular hecha de acero con una ranura *ss*, practicada á través de ella y de bordes afilados. En un lado *a* de la ranura se comprime el metal hacia arriba como 12 mm y el del otro lado *c* la misma distancia hacia abajo, de modo que aparezca como en *t*. Cuando la tuerca se atornilla hacia abajo sobre la arandela, en la dirección de la flecha, la ranura no ofrece impedimento; pero si luego tiende á destornillarse, el borde afilado superior de la ranura en *a* presenta un frotamiento contra la parte inferior de la tuerca que tiende á mantenerla en su lugar. Además, la arandela por su elasticidad tiende á recobrar su forma primitiva y comprime de este modo los filetes de la tuerca contra los del perno ó tornillo, y el frotamiento adicional producido así, también contribuye á sujetar la tuerca. Otro medio empleado es el de hacer en el extremo del perno algunos filetes de tornillo de menor diámetro que el principal *y en dirección opuesta*. La tuerca se atornilla entonces sobre el diámetro mayor y después la tuerca de retención se atornilla en la otra dirección sobre el diámetro menor, hasta que se ponga en contacto con la tuerca principal. En el perno con tuerca de seguridad **Smith**, esta segunda tuerca es solamente de ¼ de pulgada (3 mm) de grueso; después de haber sido atornillada, una de sus esquinas se plega sobre el borde de la tuerca principal.

Las arandelas de seguridad **Atwood** adquieren mayor elasticidad en la tuerca misma.

Se pretende que **si los filetes** de un perno ordinario y de una tuerca se hacen cuidadosamente de modo **que estén entre sí en perfecto contacto en toda su extensión**, no se necesita ningún arbitrio de seguridad, porque el rozamiento entre los dos filetes se distribuye sobre una superficie mayor y no se ejerce un rozamiento tan grande como si los filetes se tocaran entre sí sólo en algunos puntos, y que, por tanto, las tuercas están menos expuestas á aflojarse con sacudimientos repetidos.

Debido á la dificultad de obtener pernos y tuercas perfectos á causa del deterioro de los instrumentos cortantes que se emplean en su manufactura, se han hecho pernos y tuercas en los cuales los filetes del perno se diferencian un poco en la forma de los de la tuerca. También se hacen tuercas en las que los filetes, en lugar de ser uniformes en toda su extensión, son gradualmente más profundos y más gruesos por tener el ángulo de sus lados más agudo y su parte superior truncada. Estas tuercas se usan con pernos que tengan el filete uniforme usual. El perno entra en la tuerca por el lado donde el filete es de la misma forma que el suyo, pero sus filetes se encuentran y están forzados á un paso más angosto y más profundo por entre los filetes de la tuerca. En ambos casos la coincidencia forzada de los dos filetes produce el perfecto contacto deseado. La mayor fuerza que se requiera para atornillar la tuerca, aumenta también el rozamiento entre los filetes.

## LÁMINAS CONVEXAS

Las láminas convexas son generalmente de acero de ¼ á ½ pulg de espesor (6 ¼ á 12½ mm) y de 3 á 4 pies cuadrados (27.6 á 37 decím cuad); algunas veces son largas con varias curvaturas. La convexidad de 2 á 3 pulgadas (51 á 76 mm). De orillas planas ó con filetes, de 2 á 4 pulgadas (51 á 102 mm). Se emplean en los pisos de edificios y para puentes de calzada.

Carga total permitida, en libras, sobre una sola plancha cuadrada convexa de cualquier tamaño y espesor. Carga $= 4\,kth$, en que $k$ = la unidad permitida de resistencia en el metal, lbs por pulg cuad, unas 6,000; $t$ = espesor del metal, en pulgadas, y $h$ = flecha de la curvatura, en pulgadas. (*Obs. del T.* — Esta fórmula puede usarse en sistema métrico con aproximación suficiente poniendo en lugar de 6,000 lbs por pulg cuadrada su equivalente $6{,}000 \times .070307 = 421.842$ kg por cm cuad y las medidas de $h$ y $t$ en centímetros. Entonces viene el producto en kg.)

Las láminas convexas son más fuertes y requieren menor cantidad de concreto, etc., para su relleno, cuando se colocan con el lado convexo hacia abajo. Pesan muy poco más que las láminas planas, ó sean 10 lbs por pie cuadrado (48.8 kg por m cuad) con espesor de ¼ de pulg (6 ¼ mm).

## PESOS Y RESISTENCIA DE LOS PERNOS DE HIERRO

(Original.)

Diámetros, pesos y esfuerzo aproximado de ruptura, **para pernos redondos**; el esfuerzo de ruptura por centímetro cuadrado, se supone como sigue: Hasta 25 mm de diámetro, 20 toneladas; de 25 á 50 mm en cuadro ó de diámetro, 19 toneladas; 50 á 75 mm, 18 toneladas; 75 á 100 mm, 17 toneladas; 100 á 125 mm, 16 toneladas; 125 á 150 mm, 15 toneladas.

Una barra larga recalcada de rosca ensanchada no es más fuerte que una que no lo sea, en casos de *aplicación lenta* de cargas, ó esfuerzos. Ambas se rompen entonces hacia la mitad de su longitud, bajo igual tensión. En tales casos hágase uso de las columnas 4 y 5.

**Barras cuadradas.** Resistencia ó peso = 1.273 × resistencia ó peso de la barra redonda.

**Barras de cobre.** Resistencia = .8 × resistencia de una barra semejante de hierro.
Peso = 1.14 × peso de una barra semejante de hierro.

(*N. del T.* — Hemos convertido la tabla del autor al sistema métrico.)

**Calibrador ó hilera americana** para láminas y planchas de hierro y acero (**1893**). Omitimos las columnas del peso en kilogramos por pie cuadrado y en libras por metro cuadrado, y simplificamos los encabezamientos de las columnas restantes.

* La concordancia de los números no es sino aproximada.

El Congreso estableció un calibrador modelo para láminas y planchas de hierro y acero, en esta forma:

**El Senado y Cámara de representantes de los Estados Unidos, reunidos en Congreso, decretan**: Con el objeto de asegurar la uniformidad se establece el siguiente calibrador como medida modelo única de las láminas y planchas de hierro y acero, en los Estados Unidos de América, á saber:

| N.º | Espesor aproximado. | | Peso. | | |
|---|---|---|---|---|---|
| | Pulgadas. | Milímetros. | Por pie cuad en avoirdupois. onzas. | libras. | Por m cuad en kg. |

Y en lo sucesivo, desde el primero de julio de 1893, inclusive, ésta y no otra debe ser usada para determinar los derechos é impuestos fijados por los Estados Unidos de América, á las láminas y planchas de hierro y acero.

## MEDIDAS CIRCULARES

Usadas para comparar las secciones transversales de los alambres, etc.

La unidad circular es el área de un círculo cuyo diámetro sea una unidad lineal. Así, una pulg circular es el área (= .7854 pulgs cuads) de un círculo cuyo diámetro es una pulg. (*Obs. del T.* — De igual modo un metro circular es el área (.7854 met cuad) de un círculo cuyo diámetro es un metro.)

Hemos extractado la tabla que sigue, con autorización del autor de las importantes tablas de equivalencias de unidades de medidas de Mr. Carl Hering, Nueva York, 1888. Como nosotros tomamos 1 metro=39.37 pulgs, en lugar de 39.37079 pulgs, nuestros valores difieren algo de los de él.

**Ninguna estupidez comercial** es más insensata que la rutina de seguir con los varios calibrajes de Birmingham, etc., en vez de expresar de una vez el espesor y diámetro de hojas, alambre, etc., en milímetros ó pulgadas como desde hace tiempo se ha insinuado. Para evitar errores, que suelen ocurrir muy á menudo, por el número de escantillones en uso y por la absurda práctica de aplicar el mismo número á diferentes espesores de diferentes metales, en diferentes ciudades, lo mejor es desecharlos todos; y al hacer pedidos, determinar el diámetro del alambre y el espesor de hojas de metal en milímetros. O empléese el peso p or cien ó mil metros de alambre ó por metros cuadrados para hojas. Nosotros *creemos* que el escantillón precedente de Birmingham se aplica al cinc, cobre, bronce y plomo, aunque generalmente se dice que es para hierro y acero solamente. Usase otro escantillón de Birmingham para bronce en hojas, oro, plata y algunos otros metales; pero nunca hemos oído decir cuáles son esos otros. Hay diferentes escantillones, aun para alambres, que han de usarse con diferentes *fines;* y varias firmas tienen escantillones suyos propios, ni siquiera acordes entre sí.

Como el Sr. Stubs hace varios escantillones ingleses, el término « **escantillón Stubs** » por sí mismo no significa nada. Generalmente, sin embargo, en nuestros talleres de máquinas se aplica al escantillón de Birmingham.

**Escantillón de Birmingham para hojas de bronce, plata, oro** y todos los metales excepto hierro y acero?

★ Un mil = 1/1000 pulgada

**Las fábricas que laminan hierro en los Estados Unidos** usan generalmente el siguiente calibraje, que difiere ligeramente del de Birmingham.

| N.º | Kg por m cuad. | N.º | Kg por m cuad. | N.º | Kg por m cuad. | N.º | Kg por m cuad. |
|---|---|---|---|---|---|---|---|
| 1 | 61.025 | 8 | 33.490 | 15 | 13.718 | 22 | 6.102 |
| 2 | 58.589 | 9 | 30.464 | 16 | 12.205 | 23 | 5.468 |
| 3 | 53.707 | 10 | 27.437 | 17 | 10.643 | 24 | 4.882 |
| 4 | 48.824 | 11 | 24.410 | 18 | 9.080 | 25 | 4.394 |
| 5 | 42.717 | 12 | 21.383 | 19 | 8.299 | 26 | 3.906 |
| 6 | 39.642 | 13 | 18.307 | 20 | 7.518 | 27 | 3.515 |
| 7 | 36.615 | 14 | 15.232 | 21 | 6.835 | 28 | 3.124 |

**Cuando se pide alambre, metal en hojas, etc.,** por un número de escantillón, y no se especifica el escantillón, los comerciantes en los Estados Unidos despachan el pedido como sigue :

Latón, plata alemana en hojas, alambre de plata alemana, latón bronceado tubería de bronce, cobre ó cinc, por el escantillón de Brown y Sharpe (ó « Americano » ).

Cobre en hojas; alambre de cobre; latón sin empate, tubería de bronce ó cobre; y pequeñas barras de latón ó bronce, por el escantallón de Stubs (ó de Birmingham).

Alambre de latón no recocido ó duro tiene como $\frac{3}{4}$ de las resistencias del cuadro que sigue, y cosa de $^1/_9$ más de peso. Si es recocido, sólo la mitad de la fuerza.

**Alambre de cobre duro** puede estimarse en $\frac{2}{3}$ de las resistencias tabulares y $^1/_7$ más de peso.

**Tabla de alambre de hierro al carbón vegetal, fabricado por la Trenton Iron Co.,** de Trenton, N. J. Las cifras de la primera columna son las del **calibrador de la Trenton Iron Co.** Los diámetros correspondientes en la segunda columna se verá que son algo menores que los del calibrador de Birmingham.

| N.º | Diámetro en mm. | Metros en cada kg. | Resist, tensión aprox en kg. | N.º | Diámetro en mm. | Metros en cada kg. | Resist, tensión aprox en kg. | N.º | Diámetro en mm. | Metros en cada kg. |

(*N. del T.* — Esta tabia es la del autor convertida en unidades del sistema métrico.)

**En esta tabla el alambre** se supone duro, brillante y no templado.

Las cifras de la columna de resistencias á la tensión están basadas en experiencias practicadas con buen alambre de hierro al carbón vegetal, hechos de trozos de hierro bruto de Trenton de primera forjadura.

| | | | | |
|---|---|---|---|---|
| La resistencia á la tensión de alambres hechos de buen hierro refinado..... | es como de 15 | por 100 | menos. | que el del alambre brillante al carbón, que se da en la tabla arriba. |
| Hierro de Suecia de fundición al carbón vegetal..... | 10 | — | — | |
| Acero Bessemer dulce..... | 10 | — | más. | |
| Acero ordinario de crisol..... | 25 | — | — | |
| Acero especial ..... | 30 á 120 | — | — | |

El temple hace al alambre más dúctil y flexible, pero menos elástico y reduce la resistencia á la tensión en un 20 á un 25 por ciento.

**Para encontrar aproximadamente el número de alambres rectos que entran en un cable de un diámetro dado**, divídase el diámetro del cable por el diámetro del alambre (usando cualquier unidad); elévese al cuadrado el cociente y multiplíquese este cuadrado por .77. El resultado será exacto con sólo diferencias de 4 á 5 por ciento á lo sumo, en un cable *cilíndrico*.

**La solidez ó área metálica de todos los alambres de un cable** es al área del cable como 1 es á 1.3 próximamente. En otras palabras, el área de los vacíos es como ¼ parte del área del cable, en tanto que la de los alambres es ¾ del área de éste. Todo aproximadamente.

(*Obs. del T.* — Hemos creído más conveniente reemplazar con las seis tablas siguientes las análogas que trae el autor, porque éstas son de un solo tipo especial de vigas, que vende la Casa Carnegie de los Estados Unidos, y por tanto las que damos á continuación, tomadas de la obra Notas y Fórmulas del Ingeniero, por Laharpe, son más generales.)

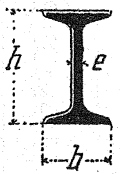
**Hierros laminados en doble T y en U.** Según el ancho relativo de las alas, se distinguen tres series de hierros, á saber :

1.° Hierros de *alas ordinarias* (abreviando AO).
2.° Hierros de *alas anchas* (AA), que se emplea menos.
3.° Hierros de *perfil normal* (PN) ó de alas medianas. El más usado.

Los dos primeros se fabrican, salvo algunas excepciones, en hierro y en acero, los PN en acero solamente Las tablas siguientes contienen los tipos corrientes. Los espesores indicados para las almas, son los espesores mínimos á los cuales se laminan los hierros. Se pueden obtener espesores más fuertes, hasta en 5 ó 6 mm de más; los anchos de las alas se aumentan entonces en lo mismo.

Dividiendo por $10^4$ los números de la columna de las I, y por $10^3$ los de la columna de las $\frac{I}{n}$, se tienen los valores de estas cantidades, expresados en metros. Los momentos resistentes ó los valores de $R\frac{I}{n}$, están en kilogrametros. Se ha admitido una carga de seguridad de 10 kg. Para valores de R = 6, 7, 8... kg, se tendrán los valores correspondientes de $R\frac{I}{n}$, multiplicando los números de la tabla respectivamente por .6, .7, .8.

## Hierros doble T de alas ordinarias (AO).



Dimensiones en mm.

| Altura *h*. | Ancho alas *b*. | Espesor del alma *e*. | Sección en mm cuad $\Omega \times 10^{3}$. | Peso aproximado en kg por metro. | Resistencia máx á la flexión — I — Momento de inercia $I \times 10^{9}$. | Resistencia máx á la flexión — I — Módulo de resistencia $\frac{I}{n} \times 10^{6}$. | Resistencia máx á la flexión — I — Para una carga de seguridad R=10 kg por mm cuad. — Momento resistente $R\frac{I}{n}$. | Resistencia mín á la flexión — H — Momento de inercia $I \times 10^{9}$. | Resistencia mín á la flexión — H — Módulo de resistencia $\frac{I}{n} \times 10^{6}$. | Resistencia mín á la flexión — H — Para une carga de seguridad R=10 kg por mm cuad. — Momento resistente $R \times \frac{I}{n}$. |

| 160 | 70 | 7.5 | 2,400 | 18.70 | 9,280 | 116.00 | 1,160 | 1,189 | 44.9 | 21.14 | 211 |
| 235 | 90 | 10.0 | 4,240 | 33.10 | 34,310 | 292.00 | 2.920 | 3.374 | 64.8 | 52.31 | 523 |

### Observaciones sobre las tablas precedentes.

1.ª Para los hierros en doble T y en U, en el caso de su resistencia máxima á la flexión, el módulo de resistencia $\frac{I}{n}$, cuando el espesor $e$ del alma aumenta en $\Delta e$, crece la cantidad : $\Delta \frac{I}{n} = \Delta e . \frac{h^2}{6}$ ; siendo $h$ la altura del hierro y quedando el perfil de las alas el mismo.

2.ª Para los hierros en doble T, en el caso de su resistencia mínima á la flexión, y para el mismo aumento de espesor $\Delta e$ del alma, corresponde un aumento del módulo de resistencia igual : $\Delta \frac{I}{n} = h . \frac{(\Delta e)^2}{6}$.

3.ª El cuadrado del radio de giro mínimo $r^2$, que figura más adelante en la fórmula de Rankine, se obtiene para los hierros en doble T y en U de estas tablas multiplicando por $n$ el módulo $1/n$ relativo á la resistencia mínima á la flexión, y dividiendo por la sección $\Omega$.

Para las doble T, $n$ es igual al semiancho del ala.

4.ª Para un pequeño aumento (epsilón) del espesor de un ángulo de brazos iguales de longitud $b$, le corresponde al módulo de resistencia $1/n$, relativo á un eje paralelo á uno de los brazos un incremento

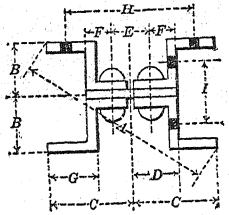
$$\Delta \frac{I}{n} = \frac{5}{18} b\ (b - 2\ e).$$

5.ª El módulo de resistencia $n$ para un eje paralelo á uno de los brazos de un ángulo, no se considera, en general, sino en el caso de una pieza formada de dos ángulos yuxtapuestos siguiendo el otro brazo y unidos solidariamente.

## COLUMNAS CARNEGIE DE BARRAS DE ACERO EN FORMA DE Z.

### Tabla de dimensiones, en mm.

Diámetro del perno ó remache = ¾ pulg (19 mm).
Con respecto al área de la sección, peso por metro, menor radio de giro, y carga de seguridad, véanse tablas, págs. 1228 á 1231.



(*N. del T.* — Hemos convertido la tabla del autor al sistema métrico.)

## COLUMNAS CARNEGIE DE BARRAS DE ACERO EN FORMA DE Z.

**Tabla de cargas de seguridad** de columnas de extremos cuadrados, como las suministran Carnegie, Steel Co. Coeficiente de seguridad = 4. Las cargas dadas están basadas en los siguientes esfuerzos en lbs por pulg cuad ó kgs por cm cuad.

Para longitudes no mayores de 90 radios de giro, 12,000 (843.715 kg por cm cuad).

Para longitudes mayores de 90 radios de giro, en lbs pulg cuad :

$$17{,}100 - 57\frac{\text{longitud}}{\text{radio}} \text{ ó bien, } 1202.13 - 4.007\frac{\text{longitud}}{\text{radio}} \text{ ; en kg por cm cuad.}$$

Cada columna está formada de cuatro barras en forma de Z y una plancha que le sirve de alma (todo de espesor uniforme), remachadas ó unidas entre sí por medio de pernos ó remaches, como se ve en la figura anterior.

## Columnas de barras de acero en forma de Z, de 6 pulgs (152 mm).

Compuestas de cuatro barras en forma de Z como de 3 pulgs (76 mm) de altura y de una plancha ó alma de 5 ¾ pulgs (146 mm) de ancho.

| | | | | | | |

**Tabla de columnas en segmentos,**

**de hierro laminado de la Phœnix Iron Co,**

410 Walnut St., Filadelfia.

Las **dimensiones** dadas están sujetas á ligeras variaciones que son inevitables en la laminación de modelos ó figuras de hierro. Los **pesos** de columnas dados son los de los 4, 6 ú 8 segmentos de que están formadas. Las **espigas** de los remaches que se usan para unirlas, de seguro que compensan la cantidad de metal extraída por el taladro al hacer los agujeros; pero las *cabezas* de los remaches aumentan el peso dado de 2 á 5 por ciento. **Los remaches se separan** 3, 4 ó 6 pulgs (7½, 10 ó 15 cm) de centro á centro.

Pueden suministrarse de **cualquier espesor que se desee.** Damos las dimensiones, peso, etc., correspondientes al espesor principal. Las columnas G son de 8 segmentos; las E, de 6. Todas las otras de 4.

(*N. del T.* — La tabla del autor en sistema métrico.)

| Marca. | Espesores mm. | **Diámetros** en milím. | | | Una columna. | | | Tamaño de los remaches. |

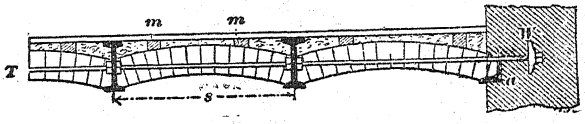
## Pisos á prueba de fuego, de vigas en I y arcos de ladrillo.

Los arcos son por lo común de « cuatro pulgs » (10 cm) ó « de medio ladrillo » de alto; luz, *s*, de 4 á 6 pies (1.22 á 1.83 m); flecha, cosa de un dozavo á un dieziseisavo de la luz. Barras T, de trabazón, de 20 mm á 25 mm de diámetro, separadas de 1.20 á 1.80, á 2.40 m y ancladas en cada muro por una placa gruesa, W. En cada muro se usa ordinariamente un ángulo de hierro, *a*, en vez de una viga. Las enjutas

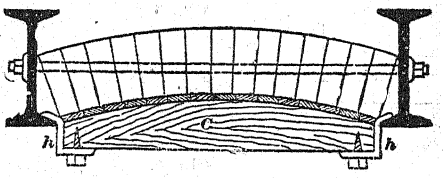


se llenan y nivelan con concreto, incluyendo listones de madera, *mm*, de 2½ á 5 cm; dos sobre cada arco. En estos listones se clava el piso.

El peso de un arco de 10 cm, con su relleno de concreto y su piso de madera, pero sin comprender las vigas, es como de 342 kg por m cuad de piso.

Una densa multitud de personas apenas pesará más de 390 kg por m cuad.

Cada centro, C, tiene adherido en cada extremo una banda de hierro, *h*, que forma un gancho por el cual está el centro suspendido de las alas inferiores de las vigas.



## LA COLUMNA GRAY

**La columna Gray**, ideada y patentada por el Sr. J. H. Gray, consiste, en su forma primitiva, en ángulos, conexionados á intervalos D (generalmente de 2 pies 6 pulgadas) (.76 m) por planchas transversales encorvadas T, ordinariamente de $9 \times {}^{3}/_{8}$ pulgadas (238 mm). Esta construcción hace las partes de la columna fácilmente accesibles, para la pintura, etc.; pero bajo fuerzas transversales tiene la columna que obrar como un marco rectangular sin diagonales. Para remediar esto se ha ideado una forma más reciente, la columna de « doce ángulos », fig. 5, teniendo, en la columna cuadrada, figs. 1 y 2, en lugar de las planchas transversales encorvadas T, cuatro ángulos adicionales, que corren longitudinalmente como se indica. Estos ángulos suplen á la columna dos almas, que se cruzan en ángulos rectos.

Las figs. 1 y 2 hacen ver la columna cuadrada, usada en el interior de los edificios; y se emplea principalmente en los tamaños de 355, 381 y 408 mm. La fig. 2 muestra planchas remachadas á los rebordes exteriores, como se hace en algunas de las columnas más pesadas. Las figs. 3 y 4 son columnas de pared y de ángulo ó rincón respectivamente. La fig. 5 muestra la columna de « doce ángulos » y la fig. 6 una de muchas formas á prueba de fuego, envuelta en bloques de « terra cotta ». Los remaches son ordinariamente de ${}^{3}/_{4}$ de pulg (19 mm) de diámetro.

La carga de seguridad, en libras por pulgada cuadrada, de la columna ordinaria, se calcula como en $17{,}100 - 57\,\frac{L}{r}$, ó sea $1202.13 - 4.007\,\frac{L}{r}$ *kg por cm cuad donde

L=largo de la columna y r=su menor radio de giro.

El costo de la columna Gray, en el taller, es de 1 á 15 centavos por lb (2.2 á 3.3 por kg) más el costo de los ángulos.

* En millares de lbs, por la fórmula : carga segura $= 17{,}100 - 57\,\frac{L}{r}$ en lbs por pulg cuad. Véase la misma fórmula en sistema métrico, pág. 981.

** Tres planchas de 1 pulg remachadas á cada par de ángulos. Fig. 2.

(*Obs. del T.*— Como la tabla anterior da los elementos de un tipo especial de columna, la hemos dejado en medidas inglesas, pero damos á continuación todas las conversiones necesarias (para las diversas unidades que aquélla trae) en ambos sistemas.

Nos permitimos recordar al lector que como el momento de inercia es un producto de cuatro dimensiones (véase § 14, pág. 490, en Resistencia de Materiales) y, si están éstas tomadas en una unidad, por ejemplo en metros, queremos hallar su valor en otra unidad, se multiplicará, ó dividirá, según el caso, por 10,000 $n$, indicando $n$ la diferencia en el orden de unidades de medida, así para pasar á milímetros se multiplicará por $10{,}000^4$.

Como una pulgada equivale á 2.54 cm ó á 25.4 mm, si queremos pasar del momento de inercia en pulgs al momento de inercia en centímetros, multiplicaremos á aquél por la cuarta potencia de $2.54 = 41.6231$, y si lo queremos en mm, por la cuarta potencia de $25.4 = 416{,}231.4256$. Para pasar de cm ó mm á pulgs se hará lo contrario.)

(*N. del T.*— Hemos dejado estas referencias para los lectores que traducen inglés ó alemán y desearen más detenido estudio de la materia.)

**1.** Para economizar material, las columnas de hierro y acero son casi siempre **huecas.** La columnas de hierro fundido son de ordinario redondas ó rectangulares, mientras que las columnas de construcción de acero son por lo común de alguna forma especial ó hechas de piezas; véanse figs. 1 á 12 y págs. 1237.

**2.** Debido al desplazamiento del molde en la fundición, las columnas de hierro fundido resultan á veces mucho más delgadas de un lado que de otro. Son susceptibles de fuerzas iniciales, debidas á la contracción desigual en el enfriamiento, y son objetables también á causa de la fragilidad y relativa inseguridad del material y su baja resistencia de tensión. Cuando el metal, para columnas muy largas, se vierte en ambos extremos del molde, puede endurecerse de tal manera que las dos porciones no se unan perfectamente en el centro; quedando así una región débil precisamente donde obra el momento máximo de flexión. El aire arrastrado por el

metal fundido produce cavidades y rebolliduras; y las impurezas, que se reunen en el fondo del molde, debilitan la fundición. (Véase también el § 14).

Véanse Columnas en General, §§ 9, 10, 13 y 35 á 43, págs. 527, etc.

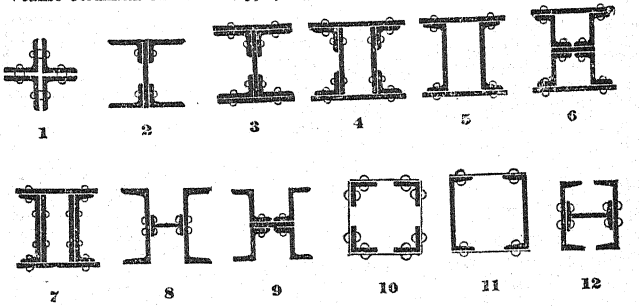

**Fig. 1 á 12.**

**3. Evítense** los diseños que, como los en *g* y en *aa*, fig. 13, sacan parte del fuste de la columna de la línea de presión produciendo **momentos de flexión** en el metal.

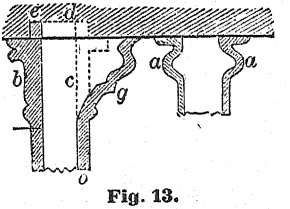

**Fig. 13.**

**4.** Usese con preferencia una forma más sencilla, como en *b*, ó una columna derecha, *ocd*, á la cual pueden adherirse cualesquiera adornos como los que se ven en *g*.

**5.** Las figs. 1 á 12 muestran **formas comunes de columnas** hechas de ángulos, planchas, piezas en U y barras en Z, de acero. Las **secciones cerradas**», figs. 4 á 7, no pueden repintarse interiormente. Sólo son convenientes, por tanto, para sitios secos en donde los cambios son ligeros. En las figs. 8, 10, 11, 12 los rebordes deben colocarse bastante distantes para permitir el remachado á máquina.

**6.** En las figs. 14 á 17, de la «Cambria Steel Co», se ven pormenores de **conexiones** entre una columna y otra y entre columnas y vigas, como se encuentran ya hechas. Las figs. 18 á 20, de la «Cambria Steel», muestran disposiciones para **bases de columnas**, que también se encuentran ya hechas.

**7. Acostúmbrase estipular que $K = L/r$ no exceda de más ó menos** 125; pero en estructuras ligeras, K excede á veces considerablemente de ese límite. Así, en once torres de transmisión, K varió de 111 á 300. Donde llegó á 300, la pieza consistía en 1 ángulo de $2 \times 2 \times {}^{1}/_{4}$ pulg ($50 \times 50 \times 3$ mm), L=120 pulgs (3050 mm); $r$=.4 pulgs (10 mm). (R. D. Coombs, Am. Soc. Civ. Engrs., Trans., vol. 61, Dic. 1908, pág. 1202.)

**8. En columnas compuestas de dos vigas en U**, enrejadas, fig. 11, las vigas están ordinariamente colocadas á tal distancia, que la tendencia de la columna será á flexarse en el plano de las almas, esto es, de modo que el mínimo radio de giro de la columna es el radio máximo de giro de la viga en U.

**9.** Siendo asimétricas las secciones de ángulo, la carga es generalmente más ó menos excéntrica. En consecuencia, la fuerza permitida para columnas de ángulo debe ser menor que la permitida para las de secciones simétricas.

**10. Los remaches están por lo común separados** >7½ cm de centro á

centro, cerca de los extremos de las columnas, en una distancia igual á dos veces el ancho de la columna. La distancia entre centros de remaches, en la línea de los esfuerzos, $>16$ veces el menor espesor de metal de las partes unidas. La distancia entre remaches, perpendicular á la línea de los esfuerzos. $>32$ veces el espesor del metal.

**11. Las barras de celosía, las planchas de tablillas y conexiones** pesan juntas el 30% ó más de las columnas pesadas, y 50 ó 60 % del peso de las columnas más livianas.

**12.** En la construcción de edificios, las **columnas pueden considerarse como de extremos cuadrados. Factor** habitual **de seguridad**=4. Véanse §§ 14 y 18.

**13.** Las columnas de ángulos ó vigas en I son generalmente de **acero blando**; las de planchas y ángulos, vigas en U, planchas ó barras en Z, se calculan por lo común para **acero mediano.**

**14. Las columnas de hierro fundido** no permiten conexiones tan rígidas, con otras columnas ó con vigas, como las columnas de acero laminado y las remachadas. No deben usarse en edificios, con un factor de seguridad menor de 8. (Véanse también §§ 2, 12, 18.)

**15. Á fin de evitar el efecto debilitante de los agujeros de los remaches,** en las columnas de acero remachadas, se emplea la columna sólida en forma de H (cuya sección transversal se ve en la fig. 21).

**Fig. 21.**

**16.** (*Obs. del T.* — La importante fórmula de Rankine, con sus coeficientes, etc., que trae el autor en esta parte, la hemos planteado y discutido en sistema métrico (siguiendo á Marvá) y hemos dejado (aunque también convertidos en unidades métricas) los coeficientes y en general los datos que sirven de base á las casas constructoras y á muchas obras importantes.)

Se aplica la siguiente fórmula de Rankine á piezas de sección cualquiera; con estos elementos :

P=carga permanente de trabajo ordinario;
R'=coeficiente de trabajo por compresión, del hierro, en kg por mm cuad empleado en modelos cortos=6;
$\omega$=sección en mm cuad cuando está en el numerador;
$l$=longitud de la pieza;
I'=menor de los momentos de inercia de la sección recta;

B=un coeficiente numérico cuyo valor es :

| | | |
|---|---|---|
| Caso 1. | Para dos bases planas (ó empotradas) | .00003 |
| — 2. | Una base plana y otra redondeada ó articulada | .000045 |
| — 3. | Dos bases redondeadas ó articuladas | .00006 |
| — 4. | Un extremo empotrado y otro libre | .00008 |

La fórmula es :

$$P = \frac{R'\omega}{I + B\frac{\omega l^2}{I'}} \text{ ; ó bien } R' = \frac{P}{\omega}\left(1 + B\frac{\omega l^2}{I'}\right).$$

El cociente $\frac{\omega l^2}{I'}$, como tiene cuatro dimensiones en el numerador y cuatro en el denominador, dará el mismo valor siempre que $\omega$, $l$, ó I' se refieren á la misma unidad de medida cualquiera que sea ésta.

Para el acero dulce de construcción se puede hacer R'=9 kg por mm cuad.

**17.** Según Rankine, en el caso 1 (bases planas ó empotradas), B=.000033. Bauschinger encontró experimentalmente que B=.000027 para hierros en que la carga de ruptura R'=31.5 kg por mm cuad. Preandeau acepta B=.00002.

**18.** En el caso 3 (dos bases redondeadas ó articuladas), Bauschinger dedujo como promedio del resultado obtenido en 27 experiencias con hierros en que el coeficiente de fractura por aplastamiento era R'=22.7 kg por mm cuad, que B=.000058.

Puede, pues, hacerse uso para el cálculo de piezas laminadas ó compuestas, de sección cualquiera, de las siguientes fórmulas :

$$P = \frac{6\omega}{1 + B\,\frac{\omega l^2}{I'}} \text{ (para el hierro)};$$

y la misma reemplazando el 6 por 9 para el *acero;* dando por supuesto á B los valores establecidos anteriormente.

**19.** M. Lebel encuentra defectuosa la fórmula de Rankine, porque no tiene en cuenta la excentricidad del esfuerzo de compresión, siendo muy frecuente que el centro de presión ó punto de aplicación de la fuerza P, no coincida con el centro de gravedad de la base, y propone para el caso de sólido de bases planas ó empotradas la fórmula siguiente :

$$P = \frac{R\omega}{.8 + .005\,\frac{dl\omega}{I'}};$$

siendo *d* la excentricidad de la compresión, ó sea la distancia del punto de aplicación de esta fuerza al centro de gravedad de la base.

(*Obs. del T.* — En los datos que siguen, aunque damos siempre su equivalencia en las unidades usadas en el sistema métrico, dejamos además los valores en medidas inglesas, porque como son los empleados por fabricantes y Compañías americanas, pueden ser de mucha utilidad para cualquier pedido, ó para cualquier estudio que pueda hacerse entre ingenieros, habituados unos á emplear solamente el sistema inglés y los otros sólo el métrico.)

## Valores de la presión máxima (s) por unidad de superficie y del coeficiente B para columnas de acero y hierro *.

Para referencias, véase lista pág. 1236.

**TS** = Máxima fuerza de tensión; $\mathbf{S}_e$ = límite de elasticidad; **PC** = punto cedente**, todo en miles de libras por pulg **(y entre paréntesis y debajo de cada cifra su equivalente en kg por cm cuad.** *N. del T*).

---

* *N. del T.* — Hemos convertido el coeficiente 1/m que trae el autor al equivalente B de la fórmula y lo damos en cien milésimas.

** *N. del T.* — Este punto lo llaman los americanos « Yield point », y como hemos consultado muchos diccionarios y varios ingenieros notables sin encontrar cómo se expresa en una sola palabra su significado, hemos resuelto llamarlo « Punto cedente », porque es precisamente el punto en que la barra sigue alargándose *sin que se aumente el esfuerzo á que está sometida* y puede considerarse como el tercer período elástico (Marva, *Mecánica aplicada*), caracterizado además porque el alargamiento se localiza y se « forma el huso » ó región de la gran contracción transversal ó *estrechamiento de sección*.

## ACERO Y HIERRO FORJADO

### Para edificios, cargas máximas (ó de ruptura).

Cambria Steel Co. Acero mediano y dulce (2). págs. 194–7.

## ACERO DE CONSTRUCCIÓN

**p**=carga media por unidad de superficie en la columna;
**s**=esfuerzo máximo por unidad de superficie en la sección transversal;
$s_s$=la misma anterior para bloques cortos;
**TS**=tensión máxima;
$S_e$=límite de elasticidad;
**K**=$L/r$=longitud dividida por el radio mínimo de giro.

(*Obs. del T.* — En lo que sigue están convertidos los resultados que trae el autor al sistema métrico. Así damos los valores de $p$, $s$, etc., en kilogramos por cm cuad; y aunque en este capítulo el autor no indica en qué unidades están TS y $s_e$ los hemos convertido suponiéndolos en miles de lbs por pulg cuad (porque así vienen hasta ahora), y los damos en miles de kg por cm cuad. Como K es un cociente que expresa la altura de la columna en *radios de giro*, es el mismo para cualquier sistema de medida.)

## Resistencia máxima de las columnas articuladas.

**Jas G. Dagron.** (Am. Soc. C. E. Trans., June 1889, vol. 20, pág. 254). 8 cols enrejadas, de sección rectangular, armadas de planchas y ángulos. Carbón .26 á .27%; TS = 5.86 á 5.91; $s_e$ = 3.58 á 3.77;
6 cols de 2 planchas de 203×6 mm, 4 áng de 57×57×6 mm; 4.88 á 7.32 m.
2 — — 228×9.5 mm, 4 — 70×70×8 mm; 7.81 m.

+ **C. P. Buchanan.** (Eng. News., dec. 26, 1907.) 7 cols de puente como sigue: Bessemer (Bess) y Martín Siemens (M. S.)

| 6 | 28.7 | 7.2 | 267 | 37.5 | 4,410 |

▲ Pruebas de 5 cilindros con extremos cuadrados cortos, en el Arsenal de Watertown (17), págs. 737-742. Diámetro=51 mm. $r$=12½ mm. L=largo de la porción redonda=228 mm. K=18. $p$, máx de 4,326 á 5,235 kg por cm cuad.

**24.** Los experimentos en cilindros pequeños sólidos de hierro fundido, arriba registrados, y muchos otros por Tetmajer (16), indican que la fórmula de Rankine es correcta en su forma; pero los experimentos prácticos con columnas cilíndricas huecas demuestran que aquellas columnas fallan bajo cargas inferiores á las dadas por la fórmula, especialmente en el caso de columnas cortas. En columnas huecas delgadas la excentricidad de la carga, que siempre ocurre, aun en ensayos cuidadosos, y mucho más en la práctica de las construcciones, concentra la mayor parte de la presión en un lado, y hace que ese lado obre sin el apoyo debido del resto de la sección. Impídese así que la columna obre como un cuerpo enterizo.

**25. Tetmajer** (16). pág. 77. encuentra que las **columnas remachadas** de acero de construcción **se conducen lo mismo que simples columnas de hierro laminado** con tal que :

(1) La distancia entre los centros de los remaches no exceda de $70 \times$ el espesor del reborde;

(2) Los remaches llenen completamente sus huecos;

(3) El debilitamiento de la sección por los huecos de los remaches $>$ como de 12 por ciento.

**26. Fracaso del puente de Quebec.** El hundimiento de la porción meridional del gran puente de *cantilever* de acero sobre el río San Lorenzo, cerca de Quebec, el 29 de agosto de 1907, durante su construcción, parece haberse debido á la falla de un elemento principal de compresión, « A9L », en el brazo de anclaje. Esta pieza, fig. 25, de 17.38 m de largo, estaba compuesta de cuatro almas, cada una de 89 á 95 mm de espesor (hecha de cuatro planchas de más ó menos 22 mm de grueso, remachadas entre sí) y de 1.37 m de ancho, provistas de ángulos de reborde de $150 \times 200$ mm y $90 \times 200$ mm, separados como en la fig. 25 y unidos entre sí por enrejado de ángulos de $100 \times 75 \times 10$ y ángulos de $90 \times 75 \times 10$ mm en la parte superior y en la base, siendo reemplazados los ángulos por planchas de $12\frac{1}{2}$ mm por espacio de varios pies en cada extremo. El radio de giro de las cuatro almas solas, inclusive los brazos más largos de los ángulos del reborde, obrando conjuntamente alrededor del eje *ab*, es de 495 mm. Esto da, para la sección entera, obrando conjuntamente, $L/r = 17{,}380/495 = 35.1$.

**27.** Según *la hoja* (*sheet*) de resistencia, aquel miembro estaba **destinado á soportar**, en servicio :

| | | |
|---|---|---|
| Carga muerta..... | 5,101,942 kg | |
| Carga viva..... | 1,823,018 | |
| Carga muerta y viva..... | 6,924,960 | $= 1{,}397.7$ kg por cm cuad. |
| Viento..... | $\pm$ 3,342,80 | |

**28.** Para miembros de compresión en que $L/r$ es (como en este caso) $< 50$, la **especificación permitía** una carga, en kg por cm cuad, de

$$840\left(1 + \frac{\text{fuerza mínima}}{\text{fuerza máxima}}\right)^{*} \text{ ó, en este miembro, de}$$

$$840 \times 1.7317^{*} = 1{,}454 \text{ kg por cm cuad.}$$

**29. La pieza parece haber sostenido**, al tiempo de su caída, una presión media de (más ó menos) 1,120 kg por cm cuad.

**30. Cada una de las cuatro almas**, inclusive el brazo más largo de su reborde, tiene, respecto de su propio eje neutro, *cd*, un radio de giro tan sólo de 25 mm (más ó menos), haciendo su $L/r > 650$. Para columnas en que $L/r$ excede de 50, la especificación permite una carga de sólo

$$.07\ (12{,}000 - 50\ L/r)\ (1 + \frac{\text{resistencia mín}}{\text{resistencia máx}}),$$

que, si se aplicara á una de estas almas, permitiría tan sólo una carga menor de 2,450 kg por cm cuad (más ó menos); pero, naturalmente, se confió en el enrejado angular y en las planchas, obligando á las cuatro almas á obrar conjuntamente.

**31.** Después del hundimiento de la estructura, sin embargo, se encontró torcido este miembro en la forma de una S y la flexión tuvo lugar en ángulos rectos á los planos de las cuatro almas, ó en la dirección en que habría ocurrido si se hubieran omitido los brazos de refuerzo. « La falla del cordón inferior A9L sirve de ejemplo como sistema de celosía ó enrejado insuficiente. » (Informe de la Comisión del Puente de Quebec.)

## Esfuerzos sobre las vigas de celosías.

**32.** « La índole poco satisfactoria de las fórmulas para columnas es muy conocida de los ingenieros, pero **las fórmulas de columnas pueden conside-**

---

* Resistencia mín = carga muerta — carga viva mín.
$= 5{,}101{,}942 - 20{,}385^{**} = 5{,}081{,}557$ kg.
Resistencia máx = carga muerta + carga viva máx + carga viva mín.
$= 5{,}101{,}942 + 1{,}823{,}018 + 20{,}385 = 6{,}745{,}000$ kg.

** *N. del T.* — El autor trae para este caso 45,000 lbs como carga viva mínima = 20,385 kg.

**rarse como fórmulas exactas comparadas con las fórmulas para celosías.** Las fórmulas de celosía fijan, de cierto modo, un valor de la resistencia máxima de las fibras en la barra del enrejado; pero sólo las pruebas y los ensayos pueden determinar si éstas dan resultados económicos y seguros. » (Informe de la Comisión del Puente de Quebec.)

**33.** El siguiente **método aproximado** (véanse comunicaciones del **prof. Clyde T. Morris**, Universidad del Estado de Ohio, Eng. News, 7 de noviembre de 1907, pág. 487; febrero 27, 1908, pág. 44) supone (1) que el diagrama de los momentos, en las columnas, es una línea recta, es decir: que el incremento de resistencia, por unidad de longitud de columna, es constante. Esta suposición hace que el esfuerzo máx, en las planchas para un mom máx dado, sea menor de lo que probablemente es; pero, por otra parte, supónese también (2) que el esfuerzo en las fibras extremas de las planchas ó vigas está uniformemente distribuído sobre la sección transversal de cada plancha ó viga. Esta suposición (porque cada porción de la plancha ó viga, entre conexiones de enrejado, puede doblarse en una ú otra dirección) hace el promedio del esfuerzo mayor de lo que es.

**34.** En una columna de celosía compuesta de dos vigas ligadas por barras que se cruzan, fig. 26, sean

$s$ = compresión permitida por unidad en la sección transversal de la columna;
= compresión permitida por unidad en trozos cortos del material dado;
P = carga total máx permitida sobre la columna;
$a$ = área de la sección transversal de la columna;
$p = P/a$ = compresión máx permitida por unidad en la sección transversal de la columna;
L = longitud de la columna;
$r$ = menor radio de giro;
V = esfuerzo total transmitido por las barras de una á otra plancha;
= mitad de la diferencia del esfuerzo entre las dos planchas;
$l$ = distancia á que se transmite V;
$v = V/l$ = incremento del esfuerzo total V, por unidad de longitud de columna;
$w$ = dist entre las líneas de remaches entre las dos planchas;
$\theta$ = ángulo entre las barras de la celosía y el eje de la columna;
$x = w.\ \cot\theta$ = proyección longitudinal de una barra de celosía;
$n$ = número de barras en cada tramo enrejado;
$vx/n$ = incremento del esfuerzo á lo largo de $x$ en una barra;
$c$ = coeficiente de la fórmula $p = s - c\,L/r$;
= un esfuerzo pequeño de la misma naturaleza que $s$;
$P_L$ = esfuerzo total longitudinal en una barra de la celosía.

**35.** Tenemos:

$$V = (s-p)(a/2);$$
= dif de la compresión por unidad × área de una de las planchas ..... (1)

$$v = V/l = (s-p)\,a/2l \ldots\ldots (2)$$

$$= \left(s - s + c\frac{L}{r}\right)a/2l = cLa/2lr \ldots\ldots (3)$$

$$vx/n = vw\cot\theta/n \ldots\ldots (4)$$

$$P_L = (vx/n)\sec\theta = \frac{v}{n}\cdot\frac{w}{\text{sen. }\theta}$$

$$= \frac{cLa}{2lrn}\cdot\frac{w}{\text{sen. }\theta} \ldots\ldots (5)$$

**36. En las columnas redondeadas ó articuladas,** la curva de elasticidad es sencilla, y tenemos, para la distancia, $l$, dentro de la cual se ha transportado V, $l = L/2$; y $L/2l = 1$. En las columnas de extremos cuadrados y fijos, la curva se voltea con dos puntos de flexion opuestas y $l = L/4$ y $L/2l = 2$. Por tanto:

$$\textbf{Con extremos redondeados, } P_L = \frac{c\,a}{r\,n}\cdot\frac{w}{\text{sen }\theta} \ldots\ldots (6)$$

$$\textbf{Con extremos cuadrados, } P_L = \frac{2\,ca}{r\,n}\cdot\frac{w}{\text{sen }\theta} \ldots\ldots (7)$$

**37.** El siguiente **método aproximado** (véase **W. C. Armstrong**, Western Soc. of Engrs, Journal, junio 1908, pág. 337) da el esfuerzo total $P_L$, en una barra

de celosía, **cuando la columna está expuesta á fallar en cualquier dirección.**

Se supone que las placas de empate soportan ¼ y la ligazón ¾ del esfuerzo cortante entre las planchas ó vigas. Sea:

$d$ = espesor de la plancha;
I = momento de inercia de la sección transversal;
$M = 2sI/d$ = momento de resistencia á la flexión en ambas direcciones; los otros símbolos como en el § 34.

**38.** Luego

$$V = M/v = 2sI/dw \quad (1)$$

$$v = V/l = 2sI/dwl \quad (2)$$

$$vx/n = 2sIx/dwln = 2s\,\mathrm{I}\cot\theta/dln \quad (3)$$

$$\mathbf{P_L} = \tfrac{3}{4}\cdot\frac{vx}{n}\cdot\sec\theta = \frac{1.5sI}{dln\,\mathrm{sen}\,\theta} \quad (4)$$

**Con extremos redondos**, $l = \mathrm{L}/2$; y $\mathbf{P_L} = \dfrac{3sI}{dLn\,\mathrm{sen}\,\theta}$ ..... (5)

**Con extremos cuadrados**, $l = \mathrm{L}/4$; y $\mathbf{P_L} = \dfrac{6sI}{dLn\,\mathrm{sen}\,\theta}$ ..... (6)

**39.** Suponiendo que las mismas barras de la celosía sean suficientemente fuertes, la integridad del sistema de celosías queda aún **limitado por la posibilidad de que se resbalen los remaches**; la resistencia contra esto, en cualquier unión, es = número de remaches × el área de la sección del remache × unidad de resistencia de los remaches á la fricción.

El prof. J. B. Johnson (Materiales de construcción, págs. 526-7) da 840 kg por cm cuadrado de la sección del remache como la **resistencia á la fricción** para los remaches de acero; 700 kg para los remaches de hierro.

**40.** « **El tamaño y la resistencia del pasador** empleado tiene un efecto apreciable en los resultados obtenidos, pero no se ha determinado el monto de este efecto. » (Informe de la Comisión del Puente de Quebec.)

**41.** « No puede esperarse que una **pieza de compresión**, de diseño y dimensiones corrientes, desarrolle un máximo de esfuerzo mucho mayor que la mitad, más ó menos, de una **pieza de tensión** hecha con el mismo material. » (*Ibid.*)

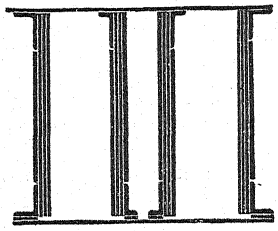

**Fig. 25.**

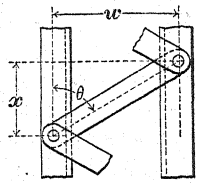

**Fig. 26.**

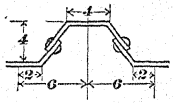
## SECCIONES, « PENCOYD », DE PISO

(*Obs. del T.* — Hemos convertido las fórmulas, etc., al sistema métrico.
L = luz, en metros;
C = coeficiente;
W = carga distribuída, en kg, por metro de ancho de piso.

$$W = .453^5 \frac{C}{L}.$$

**Pisos undulados** para puentes y edificios.
W = carga que produce un esfuerzo de fibra de 1,050 kg por cm cuadrado.

SECCION 210 M.



(*Obs. del T.* — Damos en seguida los equivalentes, en mm, de los números de la figura que indican pulgs: 4 = 102; 6 = 152; 2 = 51.)

| 17.462 | 7.45 | 10,556.88 | 50.8 | 56.62 | 84,890 |
| 19.05 | 8.642 | 12,558.62 | 57.15 | 80.46 | 101,807 |
| 20.637 | 9.983 | 14,651.53 | 63.5 | 105.79 | 125,685 |
| 22.225 | 11.92 | 17,069.57 | 69.85 | 131.12 | 152,102 |
| 23.812 | 13.41 | 19,630.14 | 76.2 | 156.45 | 180,958 |

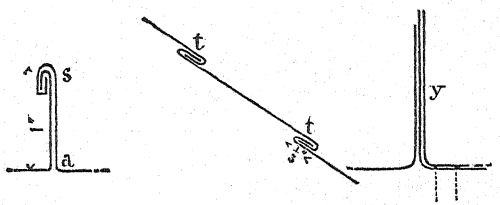
**Los eslabones de cadenas ordinarias de hierro** se hacen generalmente tan cortos como lo permita el fácil juego de ellos, á fin de que no se doblen cuando se enrollan en un tambor ó cilindro, etc., y para que sean más manuables en la suspensión de grandes trozos de piedra, etc. Experimentos hechos por orden del Gobierno de los Estados Unidos, en 1878, prueban que los clavos ó pernos debilitan los eslabones.

Cuando se hacen así, su peso por metro es aproximadamente 3½ veces el de la barra de hierro redondo de que se hacen. Desde luego que cada eslabón se compone de dos gruesos de barra; se puede suponer que una cadena tiene como el doble de la resistencia de una barra sencilla; pero la resistencia de la barra se reduce como en $^3/_{10}$ al convertirse en eslabones; de modo que la cadena tiene realmente tan sólo $^7/_{10}$ de la resistencia de las barras. Como las barras de hierro gruesas no sostienen una carga proporcionalmente mayor á la que soporta una barra delgada, de igual modo las cadenas gruesas son relativamente menos resistentes que las delgadas. En la tabla anterior se calcula 3.10 toneladas por **centímetro cuadrado** el esfuerzo medio de ruptura de una barra recta de hierro laminado ordinario de 2½ cm de diámetro ó en cuadro; en 2.94 toneladas por cm cuad el de una de 2½ á 5 cm, y en 2.79 ton por cm cuad el de una de 5 á 8 cm cuad. Deduciendo $^3/_{10}$ por cada una de éstas, tenemos como esfuerzo de ruptura de las dos barras que componen cada eslabón, lo siguiente: 2.17 ton por cm cuad hasta 2½ cm de diámetro; 2.06 ton por cm cuad, de 2½ á 5 cm, y 1.95 ton de 5 á 8 cm de diámetro. Sobre estas suposiciones está basada la tabla. Los pesos son aproximados, dependiendo de la exactitud del diámetro del hierro y de la forma del eslabón.

## ESTAÑO Y CINC

**El metal puro se vende en tejos y se llama «estaño en tejos».** Cuando está perfectamente puro (lo que rara vez sucede, pues frecuentemente lo adulteran mucho con los metales más baratos, plomo y cinc), tiene una densidad de 7.29. Es suficientemente maleable para reducirlo á láminas de sólo 0.025 mm de espesor. Su resistencia no es sino como de 323 kg por cm cuad, ó como 490 kg por cm cuad cuando se transforma en alambre. Entra en fusión á la temperatura moderada de 227° C. El estaño puro no se emplea en construcciones ordinarias, sino láminas delgadas de palastro cubiertas de estaño por ambas caras. Éstas son las que constituyen las **láminas estañadas** ó la *hojalata*, y se usan para techos, canales, etc. Para techos, se colocan sobre tablas.

**Las láminas de hojalata se disponen** como se ve en esta figura. En el taller se unen primero varias láminas, extremo con extremo, como en *tt*, doblándolas primero, luego se amartillan hasta ponerlas planas y después se sueldan. Para colocarlas en el techo se hace un rollo de ellas suficientemente grande que alcance á cubrir desde el caballete hasta el alero. Cuando se han extendido diferentes



rollos en el sentido de la inclinación del techo, se unen lateralmente doblando simplemente sus orillas, como se ve en *a* y *s*, por medio de un instrumento especial. Los maestros techadores llaman al doblez en S *doble empate*, y los más sencillos en *t*, *empate sencillo*.

Para fijar bien la plancha en las tablas, se clavan en sus bordes pedazos de hojalata de ocho á diez cm de largo por 5 cm de ancho, de 45 en 45 cm á lo largo de las juntas que han de cogerse y que están ya plegadas en S. Esto se comprenderá en la figura, en la cual la pieza del medio es el pedazo dicho antes de haber sido doblado. Los clavos deben ser de empizarrar, de cabezas más anchas que los ordinarios. Como no están expuestos á la intemperie, pueden ser de hierro ordinario.

Se usa mucho lo que llaman **estaño emplomado** (*ternes*) para techos. Es simplemente hierro en planchas cubierto con plomo en lugar de estaño que es un metal más costoso. No es tan durable como las estañadas, pero es más barato.

Las mejores láminas para estañar y emplomar son hechas de hierro de fundición al carbón vegetal (*charcoal*), que, como es más duro, soporta mejor el doblez. Las de fundición de cok, ó con hulla, se usan para planchas más baratas y son inferiores en lo que se refiere al doblez. Al hacer pedidos es importante especificar si se desean láminas de palastro al cok ó al carbón vegetal, así como también si se quieren estañadas ó de estaño emplomado.

Se usan mucho las láminas estañadas y emplomadas de acero Bessmer y otros aceros baratos. Se venden próximamente al precio de las planchas de palastro al cok estañadas y emplomadas.

También se usan para techos ciertos metales compuestos que resisten al deslustre mejor que el plomo, estaño ó cinc; pero son tan fusibles que están expuestos á derretirse con cualquier chispa ó pedazo grande de carbón encendido que cayese sobre el techo.

Un techo con cubierta de hojalata ú otro metal no debe tener una inclinación menor de cinco grados, ó sea $^1/_{12}$, y en los aleros una caída violenta al canal para impedir que el agua retroceda y se eleve por encima de la junta produciendo filtraciones.

Donde se emplea el carbón mineral como combustible, debe darse á los techos de hojalata dos manos de pintura al colocarlos y después una mano cada 2 ó 3 años. Donde sólo se usa leña no es necesario esto, y un techo de hojalata con una buena inclinación durará 20 ó 30 años.

Dos buenos obreros pueden colocar y pintar exteriormente, en un día de 8 horas de trabajo, de 23 á 28 m cuad de techo de hojalata.

Las láminas de hierro estañado se venden por cajas.

(*Obs. del T.* — La siguiente tabla se ha deducido de la del autor y en ella se expresan todas las medidas en sistema métrico.)

### Tabla de láminas estañadas (hojalata) y láminas ú hojas de estaño emplomado (ternes).

**Advertencia.** Las cajas contienen á menudo considerablemente menos peso de láminas estañadas que el que la tabla indica, pues las láminas se hacen delgadas y se estañan delgado, á fin de hacer que se pague á los mecánicos por más material que el que suministran.

Las marcas indican el espesor aproximadamente como sigue :

Láminas de mayores dimensiones pueden fabricarse para pedidos especiales; las de hierro estañado se hacen en Inglaterra; pero las de estaño emplomado se hacen también en Filadelfia y en otro lugares.

Una caja de 225 láminas 34.9×25.4 cm contiene 19.96 m cuad; pero, teniendo en cuenta lo que se llevan los dobleces, sólo cubrirá como 14 m cuad de techo. Sin embargo de que no se hace ninguna rebaja por las pérdidas que ocasionen los cortes que indispensablemente exige el ajuste de las láminas en las esquinas.

Para calcular el área cubierta por una lámina cualquiera dedúzcase 5 cm de su ancho y 2.5 cm de su longitud.

**El cinc en láminas**, colocadas del mismo modo que la pizarra, se emplea mucho para techos en algunas partes de Europa. Expuesto á la intemperie, se cubre pronto de una capa de óxido blanco, que lo protege en lo sucesivo y lo hace durable También se usan láminas acanaladas de cinc. Véase Hierro galvanizado en láminas.

Las láminas de cinc son generalmente de .91×2.13 m ó por 2.44 m. Su espesor difiere del de hierro, así : el n.° 13 es .813 mm de espesor ó 5.75 kg m cuad; el n.° 14, .889 mm y 6.59 kg por m cuad; el n.° 15, 1.067 mm, y 7.27 kg por m cuad; el n.° 16, 1.245 mm y 7.91 kg por m cuad. Cualquiera de estos números puede usarse para techos, pero debe ser de buena calidad.

Se dice que es perjudicial á la salud **el agua conservada en envases de cinc**, y recientemente se ha protestado contra los tubos de hierro galvanizado para el servicio doméstico. Sin embargo se han empleado durante muchos años en Nueva Inglaterra, en Filadelfia y en otras partes, sin ningún efecto pernicioso. Esto se debe probablemente al hecho de que siendo cortos los tubos del servicio, el agua se renueva en ellos varias veces al día y por consiguiente no permanece en contacto con el cinc y el plomo el tiempo suficiente para hacerse venenosa. Al tomar posesión de una casa debe botarse de los tubos del servicio el agua que haya permanecido estancada por algún tiempo, porque su uso hace daño á la salud.

**El cobre para techos** está generalmente en láminas de .76 m × 1.52 m =1.16 m cuad, y pesa de 4.54 á 6.35 kg cada lámina. Se colocan sobre tablas. No se usan soldaduras en las juntas horizontales como en los techos de hoja de lata; pero las juntas horizontales ásí como las del declive se forman sobreponiendo y doblando las láminas solamente, como se ve en las figs. de la pág. 998, excepto las horizontales que están dobladas ó entrelazadas, y luego muy aplanadas (la misma figura).

**Plomo en láminas.** Lista de **pesos modelos** en kg por m cuad y espesores en centímetros. (*Obs. del T.* — Hemos convertido la tabla del autor.)

| Peso en kg por m². | Espesor en cm. | Peso en kg por m². | Espesor en cm. | Peso en kg por m². | Espesor en cm. |

(*Obs. del T.* — Hemos convertido la del autor al sistema métrico.)

## Promedio de las máximas tensiones de los metales.

| El máximo de tensión por cm cuad de cualquier material, se llama frecuentemente su *invariable, coefiriente* ó *módulo* de tensión. | kg por cm cuadrado. |
|---|---|
| Antimonio fundido | 70 |
| Bismuto fundido | 225 |
| Bronce fundido | 1,652 |
| — alambre, sin temple ó duro, 5,600. Templado | 3,445 |
| — al fósforo, alambre, duro 10,500. Templado | 4,429 |
| Cobre fundido, 1,260 á 2,100 | 1,687 |
| — láminas | 2,109 |
| — pernos, 1,960 á 2,660 | 2,320 |
| — alambre (templado) | 4,214 |
| Estaño inglés en tejos | 323 |
| — alambre | 490 |
| Hierro fundido, inglés, 938 á 1,568 | 1,258 |
| — — de fundición al coke | 1,019 |
| El hierro fundido americano da un promedio de una cuarta parte más que el anterior. | |
| El hierro fundido corriente, en buen estado, estira como .00018, ó sea 1 m en 5,555 m por cada 70 kg de tensión por cm cuad hasta su límite de elasticidad, que es más ó menos la mitad de su esfuerzo de ruptura. La amplitud de su estiramiento varía mucho, sin embargo, según la calidad del hierro, como sucede con el hierro forjado. | |
| Hierro y acero laminados, véanse págs. 813, etc., 941, etc. | |
| — fundido, maleable, templado | 3,386 |

| — alambre, 1,750 á 2,100 | 1,933 |
| Plata fundida | 2,882 |
| Platino, alambre, templado, 2240. Sin templar | 3,937 |
| Plomo fundido, 119 á 168. Por el autor | 144 |
| — alambre | 115 |
| Cinc fundido, 210 á 259 (El último por el autor) | 236 |

**Las barras grandes de metal** soportan menos por cm cuad que las pequeñas. Las barras de hierro relaminadas en frío aumentan su tensión de 25 á 50 por ciento sin aumento de densidad. Se dice que pierden esta fuerza al recalentarlas.

**Empleo del plomo en las juntas de la mampostería.** Véase pág. 692. Bajo presiones generalmente menores que la fuerza de trituración de la piedra, el plomo se sale lateralmente, y, por medio de su fricción con la piedra, ejerce sobre ésta una acción desgarrante normal á la presión y tendente á rajar la piedra en pedazos cuyos ejes forman ángulos muy agudos con la línea de presión. Esto, naturalmente, debilita mucho la piedra.

**Algunas veces se coloca en las juntas de las columnas de piedra plomo en láminas**, con el objeto de igualar la presión y de esta manera aumentar la resistencia de la columna. Pero la experiencia ha demostrado que el efecto es directamente contrario y que la columna se **debilita materialmente** por este procedimiento.

## Promedio de las cargas de ruptura por aplastamiento.

Debe recordarse que estas son las cargas para piezas que sólo tienen de altura dos ó tres veces su menor dimensión. A medida que aumenta la altura, disminuye la carga de ruptura.

(*Obs. del T.* — La tabla que sigue es la del autor convertida al sistema métrico.)

| La carga de ruptura por cm cuad de cualquier material, se llama frecuentemente *constante, coeficiente* ó *módulo* de ruptura ó de compresión. | kg por m cuad. |
|---|---|
| **Hierro fundido**, generalmente..... | 5,976 á 8,788 |
| Ordinariamente se supone á razón de 7,030 kg por cm cuad. Su resistencia á la ruptura por compresión es generalmente 6 á 7 veces la de su resistencia á la tensión. Entre su límite medio de elasticidad, como de 2,362 kg por cm cuad, el hierro fundido corriente se acorta en la relación de 1 en 5555 ó 1 milímetro en 5.555 m bajo la carga de cada tonelada (2,240 lbs) por pulg cuad, ó 157 kg por cm cuad, ó como el doble del hierro forjado. De aquí que, á razón de 2,362 kg por cm cuad, se acortará como 1 en 370 ó 1 cm en 3.7 m. Los diferentes hierros fundidos pueden, sin embargo, variar de 10 á 15 por ciento en uno ú otro sentido. | |
| **El metal de cañones de la artillería de los E. U.**, como. | 12,304 |
| **Hierro forjado** dentro de sus límites de elasticidad..... | 1,574 á 2,519 |
| Su límite de elasticidad, bajo presión, da un promedio de 2,047 kg por cm cuad..... | 2,047 |
| Empieza á acortarse perceptiblemente bajo una presión de 1,260 á 1,575 kg por cm cuad, pero recobra su tamaño al quitarle dicha carga. Con 2,835 á 3,150 kg por cm cuad se acorta *permanentemente* como $^1/_{30}$ de su longitud; y con 4,252 á 4,725 kg por cm cuad, como $^1/_{15}$ por término medio. Las cargas de ruptura de la tabla, por consiguiente, no son las que absolutamente deforman el hierro forjado por completo, sino simplemente aquellas con las cuales cede demasiado para las aplicaciones más prácticas en las construcciones. Unos 630 kg por cm cuad se considera como su carga de seguridad media, en piezas no más largas de 10 diámetros; y se acortan á razón de 1 en 2,880. **El bronce** se reduce en $^1/_{44}$ parte de su longitud bajo una carga de 3,586 kg por cm cuad y la mitad bajo una de..... | 11,601 |
| **El cobre** (fundido) se desmenuza, destriza (*crumbles*)..... | 8,226 |
| — (forjado) se reduce en $^1/_8$ de su longitud con..... | 7,242 |
| **El estaño** (fundido) se reduce en $^1/_{16}$ de su longitud con 619 kg por cm cuad y $^1/_2$ con..... | 1,090 |
| **El plomo** (fundido) reduce á ½ de su longitud con 492 á 541 kg por cm cuad..... | 517 |
| Por el autor. Un pedazo de 25.4 milímetros en cuadro, 2 pulgs (51 mm) de alto, con una carga á razón de 84 kg por cm cuad, la compresión fué de $^1/_{300}$ de su altura; con una á razón de 140 $^1/_{20}$; una de 218 $^1/_5$; con una de 350, $^1/_3$; con una de 490 por cm cuad, ½ de la altura. | |
| **Peltre ó cinc** (fundido). Por el autor. 1 pieza de una pulg en cuadro (6.45 cm cuad), 4 pulgs de altura (10.16 cm) con una carga de 2,000 lbs, es de cir de 140 kg por cm cuad, se comprimió $^1/_{400}$ de su altura; con 4,000 lbs ó sean 280 kg por cm cuad, $^1/_{200}$; con 6,000 lbs (420 kg cm cuad), $^1/_{100}$; con 10,000 lbs (700 kg cm cuad), $^1/_{28}$; con 20,000 lbs (1,400 kg cm cuad), $^1/_{15}$; con 40,000 lbs (2,800 kg /cm cuad) cedió rápidamente y se rompió en pedazos. | |
| **Acero** Una carga de 15,749 kg por cm cuad lo acorta de .2 á .4. | |
| — americano. (Blach Diamond Steelwarks, Pittsburg, Penn, experimentos de Lient W. H. Shock, armada | |

de los E. U.) En piezas de 12.7 mm en cuadro y 89 mm ó de una longitud igual á 7 veces el lado.

| | | |
|---|---|---|
| **Acero** | no templado, 7,038 á 7,312 kg por cm cuad..... | 7,175 |
| — | caldeado al rojo claro cereza y sumergido después en aceite 27°7 C, 12,177 á 14,005 kgs por cm cuad..... | 13,091 |
| — | caldeado al rojo cereza claro y sumergido después en agua á 20°56 C, luego templado en una plancha caliente de 22,878 á 23,961 kgs por cm cuad..... | 23,420 |
| — | caldeado al rojo cereza claro, después sumergido en agua á 20°56 C, 19,377 á 28,123 kg por cm cuad.... | 23,750 |
| — | **Límite de elasticidad**, 2,362 á 4,252 kg por cm cuad..... | 3,307 |
| — | **La compresión** dentro del límite de elasticidad, da un promedio como de 1 parte en 13,300 con 3,300 kg por cm cuad. | |

**Los filos de las cuchillas del mejor acero** para grandes romanas de ferrocarril, se consideran seguros sometidos á una presión de 1,250 kg por cm lineal de filo, y los **rodillos** cilíndricos de acero macizo que se colocan debajo de los puentes, y que *resbalan sobre acero*, tienen una carga de seguridad de $\sqrt{\text{diám en pulgs}} \times 3100\ 000$, en lbs por pulg lineal de rodillo paralelas al eje, ó bien (*del T.*) en kg por cm lineal:

$197.33\ \sqrt{\text{diám en cms.}}$

(*Obs. del T.* — Basado en el mismo principio que produjo el radical penúltimo, en medidas inglesas, da el autor cinco fórmulas, tomadas del *Specifications for Iron Drawbridge at Milwaukee*, por Don J. Whittmore, I. C.

Estas fórmulas las hemos convertido al sistema métrico y simplificado, dando no obstante resultados con diferencias (de ocho ó diez kgs) despreciables en la práctica. Todas dan kg por centímetro lineal paralelo al eje del rodillo.)

| | |
|---|---|
| **Ruedas sólidas de hierro fundido** que corren sobre hierro forjado..... | $66.37 \times \sqrt{\text{diám en cm}}$ |
| **Ruedas sólidas de hierro fundido** que corren sobre hierro fundido..... | $52.82 \times \sqrt{\text{diám en cm}}$ |
| **Ruedas sólidas de acero** que corren sobre acero..... | $126.77 \times \sqrt{\text{diám en cm}}$ |
| **Ruedas sólidas de acero** que corren sobre hierro forjado..... | $113.54 \times \sqrt{\text{diám en cm}}$ |
| **Ruedas sólidas de acero** que corren sobre hierro fundido..... | $103.25 \times \sqrt{\text{diám en cm}}$ |

## Promedio de resistencia de las piedras á la tensión, etc.

| Las resistencias efectivas pueden fácilmente discrepar en $^1/_3$ más ó menos de las de nuestra tabla. | Kilogramos por cm cuadrado. |
|---|---|
| Ladrillo, 2.8 á 28 | 15.5 |
| Piedra de Caen, 7 á 14 | 10.5 |
| Cemento y concreto, véanse los artículos sobre cemento y concreto. | |
| Vidrio, 177 á 630 | 404.3 |
| La cola adhiere las maderas, 25 á 56 | 38.7 |
| El cuerno de buey | 632.7 |
| El marfil | 1,124.9 |
| Correas de cuero, 105 á 350. Buenas | 210.9 |
| Mortero corriente, de 6 meses, .7 á 1.4 | 1.06 |
| Mármol fuerte, blanco, de Italia | 72.7 |
| — de Champlain, jaspeado * | 117.1 |

| — rosada | 268.0 |
| Piedra artificial de Ransome | 21.1 |
| Barba de ballena | 534.3 |

* Hechos por el autor. Sección de ruptura 9.67 cm cuad.

**Promedio de las cargas de trituración en toneladas por metro cuadrado**, para piedras, etc. Se suponen las piedras colocadas *de plan en hiladas* y que sus alturas sean de **1.5 á 2** veces su lado menor. Las piedras comienzan generalmente á rajarse ó á romperse con la mitad, más ó menos, de su carga de trituración. En la práctica, ni las construcciones de piedra, ni las de ladrillo, deben someterse con confianza á más de $^1/_6$ á $^1/_{10}$ de la carga de trituración, según las circunstancias. Cuando se **hallan completamente mojadas** algunas areniscas absorbentes pierden íntegra la mitad de su resistencia.

(*Obs. del T.* — Damos la tabla que sigue en **kg por metro cuad**, deducida de la del autor, que está en medidas inglesas; cuando se desee obtener dichas cargas de ruptura expresadas en kg por cm cuad no hay más que dividir por 10,000 las que esta tabla suministra.)

| | Kg por m cuad. | Término medio en kg por m cuad. |

| Hielo duro *** | 131245 á 196867 | 164056 |

* **Ensayos hechos en el puente de San Luis**, por orden del capitán James B. Eads, I. C., demostraron que algunas piedras calcáreas que contienen magnesia, no se rompían bajo una presión menor de 12,031 tons por m cuad. Una columna de 203 mm y de 51 mm de diám se acortó en (.0025 pulg) = .063 mm sometida á presión y recobró su longitud al cesar dicha presión.

**Los ensayos hechos con la máquina de prueba del Gobierno en Watertown, Massáchusets, de 1882 á 1883**, dieron como carga máxima de trituración para el mármol blanco y el azul, procedente de Lee, Mass, 15,342 tons por m cuad; para el mármol azul del condado de Montgomery, Pa, 7,656 tons por m cuad; para la piedra calcárea de Conshohocken, Pa, 10,500 tons por m cuad; para la misma de Indiana, 5,468.21 kg por m cuad; para la piedra arenisca roja de Hummelstown, Pa, 9,187 tons por m cuad; para la piedra arenisca amarilla del Ohio, de 2,843 á 10,937 tons por m cuad. Ladrillos de Filadelfia, colocados de plan, fuertes, hechos en máquina, de 3,827 á 7,655 tons por m cuad; hechos á mano, de 7,655 á 14,218 tons por m cuad; prensados, en máquina, de 4,921 á 6,343 tons por m cuad. Columnas de mamp de ladrillo, de 33 cm en cuadro y 33 cm de altura, 100 toneladas, con cal; con cemento, 150 toneladas.

** Los ensayos hechos por el coronel Wm. Ludlow, E. U. de A., con las máquinas de ensayos del Gobierno, en 1881, dieron de 229 á 700 tons por m cuad para el hielo puro y duro; y de 174 á 207 tons por m cuad para las clases inferiores. Los trozos de ensayo (cubos de 15 á 30 cm) se redujeron de 12 á 25 mm antes de su trituración.

### Altura de trituración del ladrillo y de la piedra.

Si suponemos que la mampostería de ladrillo pesa, en número redondo, á razón de 1,800 kg el m cúb y que se rompe bajo una carga de 329 tons por m cuad, una columna vertical uniforme de dicho material de 183 m se rompería en su base por la acción de su propio peso. La piedra de Caen *, que pesa 2,082 kg el m cúb, necesitaría una columna de 419 m para su trituración. Las areniscas corrientes del peso de 2,322 kg el m cúb necesitarían una de 1,267 m, y siendo el peso del granito corriente de 2,643 kg el m cúb, requeriría una altura de 2,482 m. Pero las piedras empiezan á romperse y á astillarse con la mitad de la carga máxima de trituración, y en la práctica no se considera conveniente someterlas á una carga mayor de $^1/_6$ á $^1/_{10}$ de dicha carga de trituración, especialmente en trabajos de importancia, porque los cimientos y la imperfección de la obra de mano causan á menudo esfuerzos indebidos que obran en ciertas partes solamente.

La torre donde se hacen municiones en Baltimore tiene de altura 74.98 m y su base soporta una presión de 71,091 kg por m cuad. La base de la pila de granito de puente de Saltash (hecha por Brunel), de mampostería maciza hasta 29.26 m del altura, que soporta los extremos de dos tramos de hierro de 138.68 m cada uno, recibe una presión de 102 tons por m cuad. La base de una chimenea de ladrillo en Glasgow, Escocia, de 142.64 m de altura, soporta 99 tons por m cuad, y el profesor Rankine considera que con viento fuerte, el lado de sotavento debe soportar como 164 tons. La pila más alta del acueducto de piedra de Rocquefavour, en Marsella, es de 92.96 m y soporta en su base una presión de 142 tons por m cuad.

## VIGAS DE PIEDRA

**Tabla de las cargas netas estáticas de seguridad para vigas de granito bueno de construcción**, de 25 mm de ancho, apoyadas en ambos extremos y cargadas en el centro, suponiendo que la carga de seguridad es un décimo de la carga de ruptura y ésta de 138.4 kg para una viga de 25 mm en cuadro y 1 decímetro de luz. Se ha deducido ya la mitad del peso de las vigas, á razón de 2.72 kg por dcm cúb.

(*Obs. del T.* — Hemos convertido la tabla del autor al sistema métrico. Con el objeto de hacer más uniformes los datos de entrada á la tabla, hemos calculado las pulgadas para espesores, etc., á 25 mm en vez de 25.4, lo que produce pequeñas diferencias sin importancia en la práctica.)

| Altura de la viga. | LUZ EN METROS | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|

* Es una piedra calcárea color de crema, para edificar, traida de Caen, Francia.

(*N. del T.* — Recordando que la carga en el centro varía en proporción del ancho de la viga *b*; del cuadrado de la altura *d*, y en razón inversa de la longitud *l*, se puede calcular dicha carga por medio de esta tabla para valores de *b*, *d*, *l*, que no figuren en ella.)

**Si la carga está uniformemente distribuída en la luz,** la carga de seguridad neta será doble de la que da la tabla.

**Para pizarra de buena calidad, colocada de plan,** las cargas de seguridad pueden calcularse como triples; **para la piedra arenisca de buena clase, colocada de plan,** como la mitad, y para el mármol bueno ó piedra caliza colocados de plan, próximamente lo mismo que la de la tabla.

### Arcilla. Densidad *.

La densidad de los minerales (sobre todo los silicatos de alúmina) de que se componen las arcillas, varían generalmente entre 2, 5 y 3; la de las partes sólidas de las arcillas entre 2, 3 y 2.9 **.

Pero el peso específico de la arcilla, considerado como un material poroso, varía entre límites mucho mayores, á causa de su porosidad, la cantidad de agua que contiene, etc. Véase pág. 222, §§ 11 á 13. De esta manera encontramos los valores dados de 1.66 á 2.64 ***. Arcilla con granzón, 2.48§; arcilla de alfarería, 1.8 á 2.1; arcilla seca en terrones, suelta, 1.0.

# MORTERO, LADRILLOS, ETC.

## MORTEROS DE CAL

**Art. 1. Mortero.** La proporción de uno de cal viva en pedazos irregulares ó en polvo para 5 de arena, es más ó menos la proporción usada para el mortero común por los buenos constructores de nuestras ciudades principales del Atlántico; y si ambos materiales son buenos, y bien mezclados (dando *el punto*) con agua limpia, el mortero es tan bueno como puede exigirse para los trabajos ordinarios que no requieren una adición de cemento hidráulico. El volumen del mortero ya mezclado excede generalmente al de la arena seca y suelta en $^1/_4$ parte, más ó menos.

**Cantidad requerida.** 566 litros de arena y 113 lit de cal viva, sacudiendo ligeramente las medidas (para que se compacten), componen, más ó menos, 637 litros de mortero; lo suficiente para poner en obra 1,000 ladrillos del tamaño ordinario de 20×10×5 cm, con las juntas gruesas de mortero de 10 á 12 mm, que se dejan en los muros interiores de las casas. Con estas juntas 1,000 ladrillos de estas dimensiones hacen 1.528 m cúb de obra maciza. Casi la tercera parte del volumen es de mortero. Para las juntas exteriores, que están á la vista, donde se requiere un mortero más blanco y de mejor apariencia, los constructores aumentan la proporción de la cal de 1 en 4, ó 1 en 3. Para mortero de granzón fino cernido para muros de sótanos de piedra bruta, ú obra ordinaria de ladrillos, se usa 1 de cal para 6 ú 8 de granzón, y el mortero es bueno. En mamposterías corrientes ordinarias de piedra bruta, ó de ladrillos como se dijo antes, una tercera parte del volumen es de mortero; por consiguiente, en un m cúbico entran, más ó menos, 650 ladrillos; 368 lit de arena, y 74 lit de cal viva. Una mampostería de primer orden, de piedra bruta bien desbastada, bien hecha, contiene solamente $^1/_3$ parte de su volumen de mortero, 200 lit de arena y 40 lit de cal por m cúbico.

Para obras públicas de ingeniería, especialmente si son pesadas ó expuestas á *la humedad*, debe agregarse á los anteriores morteros una cantidad de cemento hidráulico igual á $^1/_3$ parte de la cal, ó mejor aún omitir $^1/_3$ parte de la cal sustituyéndola con igual cantidad de cemento. **Si la obra recién construída ha**

§ L. M. Haupt. Especificaciones de Ingeniería y Contratos.

**de estar expuesta al agua,** debe emplearse muy poca ó ninguna cal en el exterior.

Las que siguen son **las cantidades de mortero y de ladrillos que entran en un metro cúbico de mampostería maciza** hecha con ladrillos de 20×10×5 cm.

| Espesor de las juntas. | Proporción de mortero que entra en toda la masa. | N.º de ladrillos por m cúbico. |
|---|---|---|
| 3 mm | $^1/_9$ más ó menos | 830 |
| 6 mm | $^1/_4$ — — | 746 |
| 10 mm | $^3/_{10}$ — — | 679 |
| 13 mm | $^1/_3$ — — | 617 |
| 15 mm | $^4/_{10}$ — — | 563 |

Al hacer el cálculo de los ladrillos que entran en una obra maciza, **cuéntese con 2 ó 3% de desperdicio,** y en edificios comunes 5 % ó más. La mayor parte del desperdicio proviene del recorte de los ladrillos para ajustarlos á los ángulos, etc. En Filadelfia se calcula 1 barril de cal sin apagar para 1,000 ladrillos; ó para 2 perchas (708 lit cada una) de piedra bruta en muros de sótanos. En muros delgados entra algo menos de mortero para cada 1,000 ladrillos, que en las construcciones macizas de ingeniería, porque los primeros tienen, relativamente, más superficie que no se cubre con mortero; pero en muros delgados hay más desperdicios durante la construcción, así es que ambos requieren, más ó menos, la misma cantidad de materiales. Ensayos hechos con cuidado prueban que el mortero se endurece más y se adhiere mejor al ladrillo ó á la piedra, si se aumenta la proporción de cal. Por esta razón en nuestras obras públicas se estipula generalmente la proporción de 1 de cal viva para 3 de arena, pero probablemente no se usa nunca.

**La cal se vende generalmente en terrones por barriles** de más ó menos 104 kg netos, ó 113 kg brutos.

**Observaciones generales acerca del mortero y de la cal.** En una proporción demasiado grande de nuestras obras públicas puede verse cómo el mortero de cal se pudre y se pierde expuesto á la humedad, llevada por la acción capilar de la tierra hasta varios pies más arriba de la superficie natural, ó mucho más abajo de la superficie de los rellenos depositados detrás de los estribos, muros de contención, etc. Lo mismo se observará frecuentemente en el intradós y arranque de los arcos debajo de un relleno. *El mortero de cal, expuesto así á una humedad constante, jamás se endurecerá bien.* Aun siendo muy viejo y duro, absorbe el agua libremente. *El cemento hace lo mismo, pero se endurece.*

**El polvo de ladrillo,** ó greda quemada, mejora el mortero y lo hace hidráulico. En lugares donde no se pueda obtener arena, puede emplearse en su lugar greda quemada y molida, la cual da, generalmente, un mortero mejor.

Es absolutamente esencial **proteger la cal viva contra la humedad** y aun contra el aire; de lo contrario, se apaga espontáneamente, ó sufre el proceso llamado apagamiento por el aire, por el cual se reduce á polvo, como si fuera apagada con agua, como se acostumbra, pero sin producir calor y con poco aumento de volumen. Como el apagamiento por el aire se hace desde unos meses hasta un año ó más, según la calidad y la exposición, da lugar á que la cal absorba del aire una cantidad de ácido carbónico suficiente á dañar y destruir su eficacia. **Pero la cal viva** molida y guardada herméticamente en barriles se **conserva en buen estado por mucho tiempo.** Al molerla se reducen también á polvo las partículas refractarias que se encuentran en toda cal y que perjudican al mortero, pues no se apagan sino después de hecho y empleado. Por la misma razón es preferible no usar nunca la cal inmediatamente después de apagada, sino dejarla por un día ó dos, y aun varios, resguardada del sol, de la lluvia y del polvo, antes de hacer el mortero.

**La cal viva apagada en gran cantidad puede chamuscar y hasta quemar la madera.**

**La pasta de cal y el mortero duran años** y mejoran si se entierran bien en el suelo. Y duran meses si están bajo techo y cubiertos simplemente por una capa de arena. La pasta se contrae y agrieta al secarse, pero la arena en el mortero lo impide.

**Como un término medio aproximado,** que varía mucho según las condiciones de la piedra y el grado de calcinación, y según la finura ó grosor de la arena, si se mezcla una parte de cal viva buena en terrones ó en polvo, con una cuarta parte de agua ó menos, dará en menos de una hora hasta 2 partes más ó menos de

cal seca en polvo. Y si á este polvo se agregan 3 partes de arena seca y $^3/_4$ partes más de agua, y se mezcla bien, el resultado dará 3 ⅓ partes, más ó menos, de mortero. La misma cantidad de cal en polvo apagada, mezclada con 1 parte, más ó menos, de agua y 5 de arena, dará como 5 ⅔ partes de mortero. En ambos casos el volumen del mortero será, más ó menos, una octava parte mayor que el de la arena sola. Si para apagarla se le echan ¾ de una medida de agua, el resultado en lugar de un polvo seco, será una pasta dura de ⅛ más de volumen; ó si se le echa una medida entera de agua para apagarla, el resultado dará ¼ más de una pasta delgada, que tiene más ó menos la consistencia adecuada para mezclarla con la arena. Las cales *grasas*, muy puras, se apagan prontamente y producen de 2 á 3 tantos de polvo, mientras que las cales *magras* requieren más tiempo y aumentan menos. La lentitud para apagarse y el poco aumento de volumen, en caso de que la piedra de cal haya sido bien quemada, no son generalmente malas propiedades, sino que, por el contrario, indican generalmente que la cal es hasta cierto punto hidráulica. En este caso produce un mortero mejor, especialmente para obras expuestas á la humedad ó á la intemperie. Las cales muy puras son *cales impropias* para la intemperie y no deben emplearse sin cemento en obras importantes.

**La cal de caracoles** parece ser casi de la misma calidad que la de piedra caliza más pura; pero la cal hecha de yeso es todavía inferior y no soporta más de 1½ partes de arena, su mortero jamás se endurece mucho. Parece que las madréporas (generalmente llamadas coral) dan una cal intermedia entre la producida por el yeso y la caliza. No requieren sino calcinación mediana.

**El peso medio** del mortero endurecido es, más ó menos, de 1,680 á 1,840 kg por m cúbico.

**El mortero delgado** se prepara tan líquido que tiene la fluidez de la crema. Se usa para llenar los intersticios dejados en las juntas por el mortero común en la mampostería bruta; pero, á menos que contenga una gran cantidad de cemento, es probable que sea enteramente inútil, porque la gran cantidad de agua afecta las propiedades de la cal; y además, sus ingredientes se separan unos de otros, asentándose la arena debajo de la cal. Además, nunca se endurece completamente en el interior de gruesas masas de mampostería, y lo mismo puede decirse, probablemente, de cualquier mortero de cal. En algunos lugares se ha hallado perfectamente blando, aun después de muchos años.

Tanto la arena como el agua para el mortero de cal **deben estar libres de arcilla y de sal**. La arcilla puede quitarse lavándola, pero es en extremo difícil desembarazar de la sal á las arenas de las playas del mar aunque se laven repetidas veces. Generalmente le queda suficiente sal para conservar húmeda la obra y para producir eflorescencias de nitro en la superficie, tanto con el mortero de cal como con el cemento. Apagando la cal con agua salada da menos pasta que con agua dulce.

El mortero no debe hacerse sobre la superficie de un suelo gredoso, sino sobre una plataforma de tablones, de ladrillos ó lajas. La arena de fosos cernida y sacada del gneis descompuesto, ó de otras piedras semejantes, es excelente para el mortero, porque sus ángulos agudos hacen con la cal una masa más compacta que los granos redondos de arena de río ó playa. El mortero debe aplicarse más húmedo en tiempo cálido que en tiempo frío, especialmente en mamposterías de ladrillos; de lo contrario la mampostería absorbe demasiada agua y daña el mortero.

**La resistencia á la tensión** del mortero de buena cal en las proporciones acostumbradas de arena y cal, á los seis meses es más ó menos de 1 á 2.10 kg por cm cuad. Con menos arena ó con más tiempo, será más fuerte.

**La resistencia á la trituración** de un buen mortero de seis meses, es de 10.5 á 21 kg por cm cuadrado.

**La resistencia al deslizamiento,** ó la que el mortero común opone á cualquiera fuerza que tienda á hacer que una capa de mampostería se deslice sobre otra, según afirma Rondelet, es solamente de .35 kg por cm cuad.

**Resistencia transversal** de un buen mortero de 6 meses. Una barra de 1 cm en cuadro con una luz de 10 cm, se rompe con una carga central de .35 á .70 kg.

**La cal del mortero destruye la madera rápidamente**, sobre todo en lugares húmedos y encerrados. Sin embargo, la inmersión de la madera por una ó dos semanas en una solución de cal viva y agua, parece obrar como un preservativo.

**El hierro** incrustado completamente en el mortero, y de este modo aislado del aire y de la humedad, se ha encontrado en perfecto estado después de 1,400 años, pero si la humedad penetra en el mortero, el hierro se destruye, y es probable que lo mismo suceda con otros metales.

**El término medio de la adhesión del mortero al ladrillo ordinario**

**ó á la piedra bruta** al cabo de cualquier tiempo, será más ó menos las ¾ partes de la resistencia de cohesión del mortero para la misma época, ó sean de .84 á 1.68 kg por cm cuadrado en mortero de 6 meses. Si se tiene el cuidado de eliminar por completo el polvo, mojando bien el ladrillo en agua antes de colocarlo, ó echándole agua á la piedra con una manguera, etc., se aumentará la adhesión, pues el mucho polvo puede impedir toda adhesión. La precaución de mojar es especialmente necesaria en tiempo muy cálido para evitar que los ladrillos ó piedras calientes dañen el mortero por la absorción y evaporación rápida del agua. La adhesión á los ladrillos lisos muy prensados, ó á las piedras talladas muy lisas ó aserradas, es considerablemente menor.

## LADRILLOS

**Art. 2. Peso, tamaño, etc., de los ladrillos.** Un ladrillo de 20×10×5 cm contiene un litro; entran mil en el m cúb.

Al hacer pedidos de un gran número de ladrillos, debe especificarse el límite mínimo de sus dimensiones, para evitar engaños. Un ladrillo que tenga 6 mm menos en todo sentido que la medida dada, no tiene sino como .80 lit; necesitándose, por consiguiente, como 25% más de ladrillos para ejecutar la misma obra, y además 25% más de gasto por la obra de mano, que generalmente se paga por millar.

**El peso** de un buen ladrillo corriente de 20×10×5 cm es, por término medio, 1.875 kg ó 1.875 ton por metro cúb. Un buen ladrillo prensado del mismo tamaño tiene, por término medio, 2.08 kg. Como el peso del mortero endurecido es poco menos que el de un buen ladrillo común, podemos suponer para cálculos ordinarios el **peso de la mampostería** de ladrillos comunes, en 1.87 toneladas por m cúbico.

**Sumergidos en agua**, cualquiera de ellos absorbe, en algunos minutos, de 226 á 340 gramos de agua.

**Colocación en obra de los ladrillos.** Un albañil con un oficial que le suministre el material, puede poner en obra un promedio de 1,500 ladrillos por día de 10 horas en muros de casas comunes. En los muros exteriores (de más esmero), de 1,000 á 1,200; en los frentes bien hechos de las casas, de 800 á 1,000; en los frentes muy ornamentados de pisos bajos, de 150 á 300, según el número de ángulos, etc. En obras de ingeniería macizas y sencillas, un albañil puede colocar unos 2,000 ladrillos por día, es decir, hacer como 3 m cúb; en arcos grandes, unos 1,500 ó 2.3 m cúbicos.

Como los ladrillos se contraen al secarse y quemarse $^1/_{13}$ parte, más ó menos, de sus dimensiones, los moldes deben ser de $^1/_{12}$ parte más grandes en todos sentidos que el ladrillo quemado que se desea hacer. Los ladrillos buenos y bien quemados suenan como campanas al chocar unos con otros. En las fábricas de ladrillos cerca de Filadelfia, el trabajo de un moldeador de ladrillos es de 2,333 ladrillos por día, ó 14,000 por semana. Lo ayudan dos muchachos; uno le da la greda preparada, la arena de moldear y el agua, y el otro se lleva los ladrillos ya moldeados. Otra persona los coloca en hileras para que se sequen. Se calcula en ¾ de cuerda (montón de leña de 2.44×1.22×1.22 m) la leña que consume la quema de 1,000 ladrillos. Cuando se emplea carbón de piedra los hornos se encienden con antracita, y se concluye el cocimiento con carbón bituminoso. Con una tonelada de carbón se hacen 4,500 ladrillos.

**Pavimento de aceras con ladrillos.** Se ponen los ladrillos sobre una capa de granzón de 15 cm de espesor, libre de greda y bien consolidado. En un m cuadrado entran, empleando ladrillos de 20×10×5 cm, con juntas de 3 á 6 mm de ancho, colocados de plan, 45 ladrillos; de canto, 88, y de cabeza, 180. Un albañil regular con un peón que le pase los ladrillos y el granzón, colocará en 10 horas unos 2,000 ladrillos. Concluída la colocación se llenan las juntas con arena.

**Art. 3. La resistencia de los ladrillos á la trituración varía mucho, naturalmente.** Un ladrillo algo blando se tritura bajo una presión de 31 á 42 kg por cm cuad; mientras que uno muy bueno prensado requiere de 215 á 430 kg por cm cuadrado, ó sea, más ó menos, el máximo de trituración de la mejor piedra arenisca, ⅔ del de los mejores mármoles y piedras calizas, ó la mitad del mejor granito ó pizarra para techos. Pero los bloques de mampostería de ladrillos se trituran bajo cargas mucho más pequeñas que los ladrillos solos. En algunos ensayos hechos en Inglaterra con pequeñas masas cúbicas de sólo 23 cm por lado, asentadas con cemento, se trituraron bajo 30 á 43 kg por cm cuad. Otros hechos con pilares de 23 cm en cuadro y 69 cm de alto en cemento con sólo dos días de construídos, necesitaron de 47 á 66 kg por cm cuad para triturarlos. Otro pilar hecho

de ladrillos prensados, con el mejor cemento Portland, se dice que resistió 217 kg por cm cuadrado; y en mortero corriente de cal no resistió sino ¼ parte de dicha presión.

Debe, sin embargo, recordarse que principian á rajarse y astillarse, generalmente, bajo la mitad de la carga de trituración. Para mayor seguridad, la carga nunca debe exceder de ⅛ de la que produce la trituración; lo mismo con respecto á la piedra. Además, estos ensayos se hicieron sobre bloques bajos de mampostería y la resistencia disminuye aumentando la proporción de la altura al espesor.

La presión en la base de una torre donde se hacen municiones en Baltimore, como de 75 m de altura, se estima en 7.3 kg por cm cuad; y en una chimenea de ladrillos en Glosgow, Escocia, de 143 m (más ó menos) de elevación, en 10.1 kg por cm cuadrado. El profesor Rankine calcula que durante un temporal fuerte esta presión aumenta á 16.1 kg hacia el lado de sotavento. Con nuestros conocimientos tan imperfectos sobre esta materia, no debemos suponer que la mampostería, *con cemento*, de ladrillos prensados, aun de la mejor calidad, trabaja con seguridad bajo una carga mayor de 13 á 16 kg por cm cuadrado; ó la mampostería de ladrillos buenos, hechos á mano, á más de ⅔ partes de esta presión.

**La resistencia á la tensión** de los ladrillos es de 2.8 á 28 kg por cm cuadrado.

**La pértica inglesa** (*rod*, medida inglesa) de mampostería de ladrillos, tiene 305 pies cúbicos, ú 8.6366 m cúb, y entran en ella, más ó menos, 4,500 ladrillos del tamaño del modelo inglés; con 2.124 m cúbs, más ó menos, de mortero. *El quinta inglés de cal* es una yarda cúbica = .764 m cúb.

**Mortero helado.** Es peligroso usar el mortero común en tiempo frío. Si el frío continúa por bastante tiempo para que el mortero helado pueda fraguar bien, la obra *puede* permanecer firme ó segura; pero si hace un día de calor entre la helada y la fragua del mortero, dándole sol á un lado del muro, puede deshelarse el mortero de aquel lado y permanecer del otro lado helado y duro. En este caso el muro está expuesto á caerse, y si no sucede esto, por lo menos quedará siempre débil, porque el mortero que ha fraguado parcialmente durante la helada, al deshelarse no recobrará nunca su resistencia. Según los ensayos del autor, el cemento hidráulico parece no sufrir por la helada.

**Ensayos para hacer la mampostería de ladrillos impermeables al agua.** Extracto de una Memoria leída ante la Sociedad de Ingenieros Americanos, mayo 4, 1870, por William L. Dierborn, ingeniero civil y miembro de dicha Sociedad. Los muros del frente de la Oficina de Compuertas de Bach Bays, en el nuevo depósito del acueducto de Croton, situado al norte de la calle 86, en el Parque Central, fueron construídos con ladrillos de la mejor calidad, bien cocidos, y puestos en la obra con un mortero compuesto de cemento hidráulico de Nueva York y arena en la proporción de una parte de cemento para dos de arena. El espacio comprendido entre los muros es de 1.22 m y se rellenó con concreto.

Los muros de frente fueron hechos con sumo cuidado, y se tomaron todas las precauciones necesarias para que las juntas quedasen bien llenas y el trabajo bien ejecutado. Tienen un espesor de 30.5 cm y una altura de 12.2 m, y cuando está lleno el depósito, contiene generalmente 11 m de agua.

Cuando el estanque se llenó por primera vez y se le dió entrada al agua, se notó una filtración considerable por entre los muros. Tan pronto como se descubrió esta filtración se vació el agua con la intención de tratar de remediarla ó impedirla. Después de considerar cuidadosamente diferentes modos de lograr el objeto deseado me decidí á probar el « Procedimiento de Sylvester para evitar la humedad de los muros exteriores ».

El método consiste en usar dos soluciones ó capas para cubrir la superficie de los muros de ladrillos, la una compuesta de jabón de Castilla y agua, y la otra de alumbre y agua. Las proporciones son : 450 gramos de jabón para 5 litros de agua, y 75 gramos de alumbre para 5 lit de agua, ambas substancias perfectamente disueltas antes de usarlas.

Los muros han de estar perfectamente limpios y secos, y la temperatura del aire no debe ser menor de 10° C cuando se aplican las composiciones.

La primera solución, la del jabón, debe aplicarse á la temperatura del agua hirviendo con una brocha chata, teniendo cuidado de que no se forme espuma sobre la mampostería. Esta mano debe dejarse por 24 horas para que seque y se endurezca antes de aplicar la de alumbre, lo cual se hace del mismo modo que la primera. La temperatura de esta última solución puede ser de 15° á 21° C al aplicarse, y también se debe dejar transcurrir 24 horas para poner una segunda de jabón; las manos de dicha solución deben repetirse hasta que los muros se hayan hecho impermeables al agua.

El alumbre y el jabón así combinados, forman una composición insoluble que llena los poros de la mampostería, é impide por completo que el agua penetre en los muros.

Antes de aplicar estas composiciones á los muros del estanque, se hicieron algunos ensayos para probar la absorción del agua por los ladrillos bajo presión después de cubiertos con estas soluciones, y determinar cuántas manos podían necesitarse para hacer los muros impermeables al agua.

Para efectuar esto se hizo un cajón fuerte de madera, unido con tornillos y suficientemente grande para contener dos ladrillos, y en la parte superior se insertó un tubo de 25 mm de diámetro y 3 m de longitud. En este cajón se colocaron dos ladrillos, después de estar perfectamente secos; luego se cubrieron con una mano de cada solución, como se dijo arriba, y se pesaron. Se les sometió á la presión de una columna de agua de 12 m de altura, y después de dejarlos así durante un tiempo suficiente, se sacaron y se pesaron otra vez para saber la cantidad de agua que habían absorbido. Después de secar los ladrillos se les aplicaron otras dos manos de las soluciones, se pesaron y sometieron á la misma presión que antes, repitiendo esta operación hasta que los ladrillos no absorbieron más agua. Cuatro manos hicieron los ladrillos impermeables bajo la presión de una columna de agua de 12 m de altura.

El peso medio de los ladrillos (secos) antes de aplicar las soluciones era del .585 kg y el promedio de agua absorbida = .226 kg. Se usó un hidrómetro para probar las soluciones. Como este experimento se hizo durante el otoño ó invierno (1863), después de haberse puesto los techos provisionales á la Oficina de Compuertas, hubo que usar un calor artificial para secar los muros y mantener el aire á una temperatura adecuada. El costo fué de 10.06 centavos por pie cuadrado. Tan luego como se hubo endurecido la última mano, se hizo entrar el agua en el estanque, y los muros resultaron perfectamente impermeables; así estaban todavía en 1870, después de unos 6 años y ½.

El **arco de ladrillos** del paso del puente « High Bridge », se compone : de un arco de 9 m de radio, y de 30.5 cm de espesor; el ancho de la parte superior es de 5.18 m y la extensión cubierta fué de 128 m cuad.

Las primeras dos hiladas de ladrillos del arco son de los mejores ladrillos, bien cocidos, colocados de canto, en un mortero compuesto de una parte en volumen, de cemento hidráulico de Nueva York, y dos de arena. La parte superior de estos ladrillos y el interior de la albardilla ó coronamiento de granito, contra los cuales se apoyan las partes superiores de las dos hiladas de ladrillos, se cubrieron, después de estar perfectamente secas, con una capa de asfalto de 12 mm de grueso, la cual se colocó á una temperatura de 182° á 270° C.

Sobre ésta se colocó una hilada de ladrillos de plan sumergidos en asfalto, y colocados cuando el asfalto estaba caliente; las juntas se llenaron también de asfalto caliente.

Sobre esta capa se asentó otra de ladrillos de plan, prensados, colocados con mortero de cemento hidráulico, formando la calzada y piso del puente. El asfalto era de Trinidad y se le mezcló con un 10 % (por volumen) de alquitrán mineral y 25 % de arena. Se hicieron algunos ensayos para probar la resistencia de este alfalto empleado para unir los ladrillos; de estos ensayos se mencionan dos más abajo.

Se comprimieron juntos seis ladrillos de plan, con pega de asfalto, y se rompieron después de seis meses de colocados. La distancia entre los soportes era de 30 cm; la carga de ruptura, 405 kg; área de cada junta, 184 cm cuad. El asfalto estaba adherido á los ladrillos tan fuertemente, que en algunas partes al desprenderlo arrancó parte de aquéllos.

Dos ladrillos de punta, unidos con asfalto y comprimidos, se fracturaron después de seis meses.

La distancia entre los soportes era de 25 cm; área de la junta, 55 cm cuadrados; peso que produjo la fractura, 68 kg.

El área del puente cubierta con ladrillos asfaltados era de 2,143 m cuadrados. Se emplearon 42,728 kg de asfalto, 33 barriles de alquitrán mineral, 7.6 metros cúbicos de arena y 93,800 ladrillos. El tiempo invertido fué 109 días de albañiles, y 148 días de peones. Dos albañiles y dos peones pueden mezclar y extender en la primera mano 153 m cuadrados por día. El costo total de cada mano fué 56½ centavos por m cuadrado, fuera del derecho de importación sobre el asfalto. Atravesando enteramente el área de ladrillos é inmediatamente debajo de la primera capa de asfalto, se hicieron tres canales de 5 cm de ancho por 10 cm de profundidad, que dividieron

el arco en 4 partes iguales. Estos canales se llenaron de un cemento de pintura elástica.

Esto se hizo para contrarrestar los malos efectos de la contracción del arco en el invierno, porque se esperaba que podía ceder ligeramente en estos puntos y no en otros, y que el cemento elástico impediría cualquiera filtración.

El ensayo todo fué un éxito completo y el arco ha permanecido sin filtración alguna.

Al proponer el sistema anterior de aplicación del asfalto en la mampostería de ladrillos, el objeto fué evitar el empleo de una gran superficie continua de asfalto, como se hace generalmente para cubrir los arcos que á menudo se rajan por ser la contracción del asfalto mayor que la de la mampostería con la cual está en contacto, siendo la extensión de asfalto en esta obra solamente como de 1.6 cm cuad para cada ladrillo. Esto se cree un elemento esencial para el buen éxito de una cubierta impermeable.

Este es un método barato y muy eficaz para impedir la infiltración del agua por los arcos de acueductos y aun de los puentes. Muchas pruebas costosas con composiciones resinosas han fallado.

El cemento hidráulico parece que sólo disminuye el mal. Muchos de los inconvenientes son probablemente ocasionados por los cambios de temperatura.

**La eflorescencia blanca**, tan común en los muros, especialmente en los de ladrillos, es debida á la presencia de sales solubles en los ladrillos y en el mortero. Estas sales se disuelven y salen á la superficie del muro por la lluvia ú otra causa de humedad. El sulfato de magnesio (sal de Epsom) parece ser la causa más frecuente de este defecto. En mucho lugares se hace la cal para mortero de delomita, ó piedra caliza, *magnésica*, que muchas veces contiene 30%, ó más, de magnesio; ésta se encuentra también muchas veces en la arcilla de ladrillos. El carbón de piedra, generalmente, contiene azufre, más á menudo en combinación con hierro, formando las bien conocidas « piritas de hierro ». La combustión del carbón al quemar la piedra caliza ó greda, en las fábricas, en las cocinas, etc., convierte el azufre en gas ácido sulfúrico, el cual cuando se pone en contacto con el magnesio y el aire, como en los hornos de cal ó de ladrillos, ó en los muros ó chimeneas, se convierte en ácido sulfúrico, y se une con el magnesio, formando el sulfato soluble. No conecemos medio alguno que impida su presencia en tales circunstancias, pero la formación del sulfato puede evitarse con el uso, para ladrillos, de la piedra caliza y de la greda libres de magnesio.

# MORTERO DE CEMENTO

## Cemento.

**Para experiencias y práctica**, véase pág. 1346.

**Para especificaciones**, véanse págs. 1278, 1280, 1401.

**Para concreto**, véanse págs. 1295, etc.

**1. Hidraulicidad** es la propiedad de fraguar y endurecerse bajo el agua; los **cementos** que se endurecen en el agua se llaman **cementos hidráulicos** ó por brevedad, **cementos**. Para los fenómenos que se producen **al mezclar cementos con agua**, lleven ó no arena, véase « Mortero », pág. 1287.

## Materiales.

**2. Las substancias que ejercen mayor influencia** en los morteros de cal y cemento son:

| | | |
|---|---|---|
| Calcio, | Ca | Oxígeno, O. |
| Aluminio, | Al | |
| Carbón, | C | |
| Sílice, | Si | |
| Hidrógeno, | H | |

**3. El oxígeno se combina con cada uno de los** otros para formar **óxidos**, así :

Oxido de calcio CaO, que es cal;
Sexquióxido de aluminio, $Al_2O_3$, es alúmina;
Bióxido de carbón, $CO_2$, es ácido carbónico;
Bióxido de sílice, $SiO_2$, que es ácido silícico;
Oxihidrógeno, $H_2O$, que es agua.

**4. Los elementos** más usados en la fabricación de cementos son : (a) *Calcáreos*, (b) *substancias arcillosas*, ó (c) ambos, calcáreos y arcillas.

(a) **Calcáreos** (ricos en carbonatos de cal).

**Piedra caliza**, carbonato de cal, ó una combinación de cal y ácido carbónico, $CaO+CO_2=CaCO_3$. El mármol es una caliza.

**Dolomita, ó caliza magnésica** que contiene un 45% de carbonato de magnesia, $MgO.CO_2$. Cuando las capas de caliza y dolomita están juntas, la roca varía en su composición entre ambas, conteniendo proporciones de carbonato de magnesia variables entre 0 y 45.

**Una caliza blanda** (como fango consistente), formada por restos de conchas marinas.

**Marga** (*marl*), un carbonato de cal hidratado, blando é impuro, precipitado en aguas tranquilas, se encuentra en los lechos y orillas de lagos existentes ó extintos.

**Residuos alcalinos**, carbonato de cal, precipitado como un residuo en la fabricación de soda cáustica.

**Coral**. (Véase el § 5.)

(b) **Substancias arcillosas** (ricas en silicatos de alúmina).

**Arcilla** (incluyendo las substancias arcillosas minerales en general), un silicato de alúmina ó combinación de alúmina con ácido silícico, $Al_2O_3+SiO_2$.

**Esquistos arcillosos**, arcilla solidificada por proceso geológico.

**Puzolana**, escoria volcánica que se encuentra en Puzzuoli, cerca del Vesubio, es un silicato de alúmina impuro.

**Escorias de fundición**, que son como puzolanas artificiales.

**Polvos de ladrillo**. (Véase el § 6.)

(c) Ricos en **carbonato de cal y silicato de alúmina**.

**Las rocas propias para cemento** son calizas arcillosas. Contienen generalmente de 13 á 35% de silicato de alúmina; y el carbonato de magnesia en proporción hasta de 25%.

**5. Roca blanda de coral** de los cayos cerca de Colón (Panamá), mezclada con arcilla y fango que trae el río Chagres, ó con tobas que se encuentran en el istmo ó con ambas molidas, quemadas y ensayadas en el « Lehigh Valley Testing Laboratory », en Allentown, Pensilvania; dieron un cemento uniforme comparable á las marcas corrientes de los cementos de Lehigh. La roca de coral es un carbonato de cal notablemente puro. La arcilla y el fango del Chagres son pobres en sílice, pero contienen buena cantidad de hierro en proporción á la alúmina. Las tobas tienen más ó menos la misma composición que las substancias arcillosas empleadas en Lehigh.

**6.** El Sr. Ernest McCullough « mezcló polvo fino de ladrillo con cal hidratada y produjo un cemento satisfactorio para un pequeño trabajo de concreto en un sitio donde no pudo fácilmente obtener cemento Portland ».

**7. Cal**. Cuando se queman las calizas (sin arcilla) se va el $CO_2$ y el producto que es **cal viva** tiene gran afinidad por el agua, y la absorbe con tal avidez, que desarrolla calor suficiente para producir vapor, y éste desintegra y aumenta el volumen de la masa. Combinada así con el agua, se forma un hidrato de cal, $CaOH_2O=CaH_2O_2$. Esto es **apagar** la cal y se la llama **cal apagada**. Cuando se emplea en los morteros, absorbe gradualmente ácido carbónico del aire y se forma carbonato de cal, evaporándose el agua. Los morteros de cal endurecidos pueden considerarse como una caliza artificial.

## Fabricación.

**8. Cemento**. Cuando se quema un silicato de alúmina, como la arcilla, en cantidades suficientes con un carbonato de calcio, como una caliza, el producto, llamado cemento, aparece aún sin **fraguar** (sin apagarse); pero por otra parte los elementos combinados de la cal, la alúmina, la sílice y el agua formados durante la quema, son tales, que luego en el mortero reaccionan rápidamente bajo, la acción del agua. Los químicos no están de acuerdo sobre la naturaleza de estas combina-

ciones, excepto en que constituyen un proceso de cristalización, producido principalmente por la formación del silicato y el aluminato de cal hidratada, cuyos componentes constituyen la mayor porción de casi todos los cementos.

## Cemento natural y Portland.

**9.** En la fabricación del cemento **natural** las rocas de cemento quebradas en terrones se calcinan entre 1000 y 1400° C (1800° á 2500° F) en un horno fijo empleando como combustible capas alternadas de carbón triturado al tamaño de un guisante; luego se muele, muy fino, y este polvo se mezcla bien para lograr la mayor uniformidad.

**10. La calidad** de los cementos naturales varía mucho con las diversas composiciones de las rocas empleadas.

**11.** El nombre de **Rosendale**, original y propiamente restringido á los cementos naturales fabricados en el condado de Ulster, Nueva York, se ha aplicado indistintamente á todos los cementos naturales americanos en general.

**12.** En Europa llaman **cemento romano** á los naturales de fragua rápida.

**13.** El **cemento Portland** es llamado así por su semejanza, cuando ha fraguado, con las piedras calizas de Portland, en Inglaterra.

**14.** El **cemento Portland** se hace por las diferentes combinaciones de calcáreos y substancias arcillosas mencionadas en el § 4, y esto requiere diversos procedimientos preliminares. Así, las rocas duras se trituran; las blandas y las arcillas se muelen; las arcillas se mezclan húmedas y á veces cuando están fangosas se bombean para llevarlas á la fábrica. Siempre el producto se seca y se muele muy fino, se mezcla, y luego se calcina á una temperatura de 1450° C á 1500° C, hasta que se inicia la vitrificación, que consiste en la combinación química de la sílice, alúmina y cal, en escorias vítreas (*clinker*) que son silicatos dobles de alúmina y cal. Estas escorias (*clinker*) se vuelven á moler hasta convertirlas en un polvo impalpable que constituye el producto definitivo.

**15. Las proporciones** de los diversos elementos se gradúan cuidadosamente. Éstas son generalmente de 74 á 77.5% de carbonato de cal y un 20% de silicato de alúmina y óxido de hierro. (Véase § 32.)

**16. Manipulación.** Con el material bruto se forman á veces ladrillos que se queman en hornos fijos; pero ya se usa más llevarlo molido en polvo fino á hornos rotatorios de 6 á 8 pies (1.80 m á 2.40 m) de diámetro y de 60 á 100 pies (18 m á 30 m) ó más de largo. El carbón en polvo como combustible es impelido por el otro extremo y por medio de un inyectador de aire. El aire requerido para la combustión entra libremente por otras aberturas.

**17.** Como sucede con la cal, **la combustión** expele el ácido carbónico y el agua y completa la oxidación del hierro.

**18. El mayor costo del cemento Portland** se debe á la esmerada selección de los materiales y á la costosa elaboración, todo lo que permite obtener mayores resistencias y uniformidad que en los cementos naturales.

**19. Las mejoras** alcanzadas en la fabricación del cemento Portland ha disminuído el empleo de las otras clases. Debido á la mayor cantidad de arena que soporta los constructores lo usan aun en los casos en que les es permitido usar los naturales.

**20.** Si el material es deficiente en cal, puede **quemarse demasiado** (exceso de arcilla). La falta de quema (crudeza) produce un *clinker* blando color moreno, de fragua muy rápida que se calienta á la acción del agua. Algunos cementos de fragua lenta se hacen más rápidos después del almacenaje.

**21.** El **cemento Portland** se usa en construcciones sometidas á fuertes ó frecuentes resistencias, en casos en que se requieren elevadas resistencias en breve tiempo, para construcciones de concreto, cuando la obra va á estar en contacto con el agua, en muros delgados sometidos á la presión de las aguas, y para obras expuestas á altas temperaturas; mientras que los **cementos naturales** pueden emplearse en fundaciones secas y abrigadas y que no vayan á resistir presiones mayores de 75 lbs por pulg cuad (5.27 kilogramos por cm cuad) y no aplicables sino tres meses después de construídas, para sostener y rellenar muros de piedra y de concreto donde sólo influyen el peso y el volumen, y para cimientos (bases) de calzadas y de cloacas.

## Puzolanas.

**22. Cementos de escoria** (llamados á veces cementos de puzolana ó simplemente *puzolana*). Son mezclas íntimas de cal apagada y escorias de horno, ambas bien molidas, sin calcinar. A medida que las escorias van saliendo del horno, se

enfrían y desintegran echándolas en el agua. A veces se le agrega un poquito de soda para precipitar la fragua. No se confunda el cemento de escoria con los Portland en que se emplean las escorias como ingredientes.

**23.** En el aire seco, los sulfuros, contenidos en los cementos de puzolanas, se oxidan y producen grietas superficiales. Fraguan más despacio que los Portland á menos que se les ponga soda. Tratados así, la soda se convierte en carbonato después de prolongado almacenaje y el cemento vuelve á hacerse de fragua lenta. Como los cementos de puzolanas, bien hechos, no contienen cal libre ni anhídrica, no se deforman ni se hinchan, y requieren menos agua que los Portland; pero para su estabilidad es necesario que la construcción se mantenga húmeda. Se los recomienda para ser empleados en agua salada, solos ó mezclados con Portland. El mortero hecho con ellos es duro, pero nunca alcanzan la resistencia de los Portland. No deben estar expuestos á frotamientos ó golpes.

**24.** Se dice que los **cementos de puzolana** dan buen resultado empleados con 2 ó 3 partes de arena y no expuestos á temperaturas bajo 0° C. Los ingredientes deben estar muy bien molidos é íntimamente ligados. Se usan cuando no se requiere gran resistencia y dureza.

## Cementos silícicos.

**25. Cementos silícicos, ó arenosos.** Se hicieron en su origen mezclando al cemento Portland arena de cuarzo (sílice) y moliendo la mezcla hasta la extrema finura. Se asegura que el cemento así preparado se puede moler más fino y que estos cementos silícicos, en proporciones de una parte de cemento Portland y tres de arena, pueden soportar en el mortero casi tanta arena como el cemento puro; también se asegura que los morteros de estos cementos son menos permeables al agua que los ordinarios de cemento puro.

**26.** Debido al gran costo de la molienda de arenas cuarzosas, se las sustituye ahora con materiales menos duros, como las **piedras calcáreas**. El producto así obtenido se llama todavía « cemento silícico », aunque contiene menor proporción de sílice que el mismo cemento Portland.

**27. Los cementos silicados** dan morteros que se prestan más suavemente al trabajo de cuchara que los otros.

**28.** En la construcción de una esclusa de concreto en San Pablo (Minnesota) se trató de usar 1.5 volumen de cemento silícico, como equivalente á 1 volumen del cemento Portland marca « Saylor »; pero las pruebas demostraron que, á los 6 meses, el concreto hecho con cemento silícico era **tan fuerte** como el de Portland.

## Otros cementos.

**29. Cemento Portland blanco;** se obtiene haciendo ciertas modificaciones en la fabricación y es casi incoloro. Sirve para imitar mármol, etc., y se presta para recibir un colorido artificial. Es más caro que los Portland corrientes. (Véase § 44.)

**30. Cemento de minerales de hierro** ( « Erz-cement » ) Krupp steel Co. En este cemento las substancias arcillosas del Portland están casi en su totalidad reemplazadas por el óxido de hierro. Los elementos se queman y se muelen como para el Portland. Véanse §§ 13, etc. Densidad 3.31, fragua más lenta que el Portland. Su resistencia al principio es baja, pero luego supera la del Portland. No tiene expansión, ni se agrieta en agua salada bajo 15 atmósferas. (Wm. Michaelit Jr. Western Soc. of Engeneers, vol 12 n.° 4, agosto 1907; S. B. New-Berry, « Cemens Age », enero 1907.)

**31. Cal hidráulica** es el nombre dado á algunos cementos (muy usados en Europa), los cuales, aunque hidráulicos hasta cierto punto, no contienen suficientes elementos de hidraulicidad para impedir la efervescencia; ésta, no obstante, es más lenta, y menor el aumento de volumen que en la cal corriente.

## Composición.

**32. Análisis de los cementos.** Percentaje.

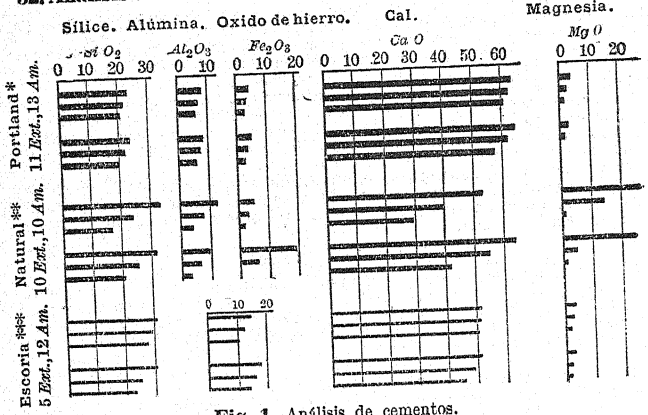

**Fig. 1.** Análisis de cementos.

(*Obs. del T.* — Los números 0, 10, 20, que están *dentro* de la figura debajo de la segunda y tercera columnas de rayas horizontales, se refieren á la combinación de alúmina y óxido de hierro. En cada grupo de 3 líneas, la superior indica el máximo percentaje; la intermedia, el mediano, y la más baja, el mínimo. Ext significa extranjeros; Am, americanos.)

**33.** La proporción en peso entre el silicato de alúmina y la cal en un cemento, es su **índice de hidraulicidad**.

**34.** Así, un cemento que contenga 30% de silicato de alúmina y 60% de cal, tendrá como índice de hidraulicidad $^{30}/_{60} = .50$.

**35. El módulo hidráulico** es aproximadamente el **inverso** del índice de hidraulicidad, es decir: el módulo es la proporción en peso de la cal para la sílice, la alúmina y el óxido de hierro. A veces se especifica que el módulo en el cemento Portland debe ser 1.7.

**36.** En los cementos naturales el módulo varía generalmente de .667 á 1.667.

**37.** Mr. Spencer B. Newberry emplea la siguiente proporción: (cal — alúmina) ÷ sílice, la cual llama él coeficiente de cal y éste varía en el material bruto de 2.7 á 2.8, y en los mejores cementos comerciales de 2.5 á 2.6.

**38.** Mr. Edwin C. Eckel (Cement Limes and Plasters, pág. 170) indica el siguiente,

$$\text{« Índice de cementación »} = \frac{2.8\,s + 1.1\,a + .7\,hi}{c + 1.4\,m}$$

en donde $s$, $a$, $hi$, $c$, $m$, son el percentaje en peso de sílice, alúmina, óxido de hierro, cal y magnesia respectivamente.

**39.** Con lo que generalmente se adulteran los cementos, es con calizas molidas, cal, pizarra, escorias y cenizas; y al Portland lo adulteran con cementos naturales. La mayor parte de los adulterantes son inertes y por tanto sólo debilitan el cemento, pero la cal viva hace muchos más graves daños. Véase Morteros de cemento, §§ 28, etc., pág. 1289.

---

* Richard K. Mende, « Portland Cement », 1906, págs. 16, 17.

** Edwin C. Eckel, « Cements Limes and Plasters », 1907, págs. 253, etc.

*** 16 análisis del « cemento de escoria de acero » fabricado por la « Illinois steel Co », al sur de Chicago, según informes de la comisión de ingenieros del Gobierno americano, 1900, dieron el mismo promedio, pero, generalmente con mayor uniformidad: sílice, 29.9 á 27.8; alúmina y hierro, 12.1 á 11.1; cal, 52.1 á 50.3; magnesia, 3.0 á 1.6.

## Propiedades.

### Fineza.

**40. Fineza.** Aun en los cementos de fineza normal, la parte interior de los granos parece que permanece inerte. Mientras más molido está el cemento, más arena resiste en los morteros, y no obstante éstos alcanzan la fuerza requerida. Pero en en todo caso hay un límite en el cual el mayor costo para darle mayor fineza destruye la ventaja dicha.

**41.** De aquí que la fineza es menos importante en los naturales que en los Portland; pues la baratura de los naturales hace que se puedan emplear éstos en mayor proporción, en vez de gastar en molerlos más finos, para darles más fuerza.

**42.** Los cementos molidos á una **exagerada fineza**, para alcanzar mayores resistencias que la de los cementos comerciales, fraguan tan rápidamente que tienen que usarse inmediatamente que se les agrega el agua.

**43. La fineza del cemento y de la arena son las siguientes**, donde los números grandes representan los grados de los cedazos, los pequeños á la izquierda de aquéllos representan el percentaje que queda en los cedazos, y los números pequeños á la derecha representan el percentaje pasado por el último cedazo. Los números pequeños suman=100. Así, $^{5}20\ ^{15}30\ ^{35}40^{15}$ significa que en el cedazo n.º 20 quedó 5% en el 30, 15% y en el 40 quedó 35% y el último 45% pasó por el cedazo n.º 40.

### Color.

**44.** Los silicatos y aluminatos de cal que propiamente constituyen los cementos, son incoloros, cuando están puros (véase cemento blanco, § 29). Por consiguiente, el color de los cementos se debe á otras materias cuya presencia es inevitable; en especial, los óxidos de hierro, que pueden ser afectados por ingredientes, benéficos, dañinos ó neutrales. De aquí que el color en sí no es un indicio para la calidad; pero **las diferencias de tinte**, en un cemento dado, pueden indicar diferencias en las rocas empleadas ó en el grado de cocción. Así, en los cementos naturales, un color claro indica casi siempre rocas de calidad inferior ó incompleta cocción. Un cemento de grano grueso, de color claro y liviano, es muy sospechoso.

**45.** « En los cementos Portland el color gris ó gris verdoso se considera como el mejor; gris azulado indica probablemente exceso de cal, y color pardo un exceso de arcilla. Los cementos naturales son generalmente pardos, pero varían de claro á obscuro. Los cementos de escoria tienen un tinte morado como lila suave. » (Prof. Ira O. Baker, « Tratado de construcciones de mampostería », pág. 55.)

### Peso.

**46. Densidad y peso.** Sobre densidad, véase el Resumen de especificaciones págs. 1278 y 1280. La densidad de las partículas sólidas del cemento no varía con el grado de fineza, pero disminuye por la absorción del agua y del ácido carbónico al aire libre y por tanto se aumenta al secarse. La densidad de los Portland puede variar entre 2.9 y 3.25, ordinariamente de 3.0 á 3.2; los cem naturales, entre 2.7 y 3.2; los puzolanos, entre 2.7 y 2.9.

**47.** El peso del cemento en polvo varía con la exposición al aire libre ó la secada, como ya se dijo, y aumenta con la compresión por ej. : cuando es embalado. Se reduce con la fineza, pues las partículas pequeñas al embalarlo se compactan menos. Faija encontró una pérdida en peso de 6% pocos días después de molido; 17% en seis meses y 21% en un año.

**48.** En un cem Portland alemán, Eliot C. Clarke encontró 1.44 kg por litro, cuando el 40% había quedado en el cedazo n.º 120, y 1.20 kg cuando todo pasó por el mismo cedazo.

**49.** Aproximadamente el cemento Portland se calcula en 100 lbs y los naturales en 75 lbs por pie cúbico (ó sea 1.61 kg por litro los primeros y 1.20 kg los naturales).

### Embalaje.

**50.** Debido á las variaciones de la densidad de los cementos, varían también el tamaño y peso de los bultos en que se embalan. La práctica comercial es vender un barril de cem Portland de 400 lbs bruto (181 kg) incluyendo el barril; el natural 300 lbs bruto (136 kg).

**51. Un barril de cem Portland** tiene de 2 á 2.2 pies (.61 á .67 m) de alto entre las tapas y 1.38 á 1.46 pies (.42 á .45 m) de diámetro medio. Pesa de 21 á 29 lbs (9.5 á 13 kg) y está forrado interiormente en papel. Su volumen es

de 87.7 á 99 litros, pero el cem comprimido en él ocupa de 106 á 121 litros suelto y pesa de 168 á 177 kg.

**52. Un barril de cem natural** pesa como 20 lbs (9 kg). En los Estados del Oeste contiene 120 kg, en los del Este 136 kilg.

**53, 54, 55.** (*N. del T.* — Estos números no tienen sino importancia muy local.)

**56.** El cem que no se exporta se embala generalmente en sacos de papel fuerte ó de tela.

**57, 58** y **59.** (*N. del T.* — Sólo tienen importancia local.)

## Edad del cemento.

**60.** La edad del cemento se traduce por el mayor ó menor apagamiento de la cal que le queda después de la quema. El buen cem Portland mejora dejándolo por algunas semanas expuesto al aire seco; no obstante, si se mantiene demasiado seco se deteriora á la larga con lentitud; pero los cementos naturales sufren generalmente expuestos al aire, y, en general, todos los cementos, compuestos como están por materiales dotados de gran afinidad por el agua, se deterioran expuestos á la humedad. Por lo tanto es conveniente preservarlos hasta de la excesiva humedad del aire. Con esta precaución, aunque se retarde su fragua, no se deteriora apreciablemente en muchos meses.

**61.** El almacenaje con presión lo apelmaza, pero esto no es signo de deterioro.

**62. Restauración por requema.** Los cem que se deterioran por el aire pueden en gran parte restaurarse recalentándolos al rojo.

**63.** Si el cem **se almacena en lugares calientes**, puede adquirir la propiedad de estallar (*flash*) al contacto del agua, y además fragua con mucha más rapidez.

## Pruebas.

Véase en los capítulos subsiguientes todos los Ensayos.

**64.** Aunque los **ensayos químicos** de los cementos se hacen con más precisión en los laboratorios, los ingenieros pueden hacer la siguiente sencilla prueba. Tratado por el ácido clorhídrico « el cem Portland puro hace una ligera efervescencia, produce un gas acre, picante, y forma gradualmente una como gelatina de color amarillo brillante sin sedimento. La piedra caliza ó roca con que se fabrica el cem mezclada con él, produce fuerte humo, hasta que se haya descompuesto todo el carbonato de cal y luego se forma una especie de gelatina amarilla. La arena de cuarzo queda sin disolverse. Deséchense los cem que contengan estos adulterantes ». Judson, « City Roads and Pavements ». La presencia de escorias se descubre generalmente por el azufre que contienen y que da un aspecto lechoso si se agita el cem en una solución de ácido clorhídrico en agua.

**65.** Fuller y Thompson encontraron que los cem que no soportaban este ensayo no tenían la fragua debida y los que lo resistían también sufrían con buen resultado otros ensayos químicos más concluyentes.

**Propiedades y ensayos del cemento. Informe de la comisión de ingenieros nombrada por el Gobierno de los E. U.** Propiedades y ensayos de los cementos Portland, naturales, y puzolanas *. Extracto de un informe de los mayores W. L. Marshall y Smith S. Leach y el capitán Spencer Cosby, ingenieros nombrados para hacer ensayos de cementos, 1901.

Desgraciadamente, las pruebas para la aceptación ó rechazo se hacen en los productos que aún no han alcanzado su final evolución. Cuando un cemento entra á formar parte de una mampostería está durante varios meses sufriendo alteraciones químicas, mientras que pocas veces es posible hacer ensayos con él por más de algunas semanas á lo sumo.

Pocas pruebas bien hechas valen más que muchas hechas á la ligera.

Los cem almacenados por mucho tiempo deben ser cuidadosamente probados antes de emplearlos, para apreciar su deterioro. Se debe rechazar todo cem sin tomar en cuenta la proporción de fallas en las pruebas hechas, si las muestras comprueban alguna peligrosa variación en la calidad por defectos de manufactura que quitan al producto su uniformidad.

La costumbre **de ofrecer primas** á los cementos de extraordinaria resistencia **es muy objetable**, pues esto hace que se produzcan cem con defectos difíciles de averiguar.

Para los cementos Portland ó puzolanos háganse **pruebas** de (**1**) fineza; (**2**) densidad; (**3**) constancia de volumen; (**4**) tiempo de la fragua; (**5**) resistencia á la tracción. En los cem naturales omítanse las (2) y (3).

(**1**) **Fineza.** La cualidad de adhesión del cem reside sobre todo en la mayor fineza alcanzada en la molienda. Usese un cedazo n.º 100 hecho con alambre de cobre, calibre n.º 40 Stubs; **zarandéese** el cedazo hasta que no pase más cem. El tanto por ciento colado se determina pesando el que no ha pasado.

El cedazo debe examinarse con frecuencia para ver si los alambres no se han separado más.

(**2**) **Densidad.** La prueba de la densidad es importante para conocer si un cem Port ha sido adulterado. Mientras más elevada sea la temperatura de la quema hasta el límite de la vitrificación, mejor será el cem y mayor su densidad. Si no ha sido bien quemado, la densidad del Port puede bajar de 3; si se ha pasado del punto de quema requerido, la densidad puede llegar á 3.5. Los cem naturales tienen una densidad de 2.5 á 2.8 y los puzolanos de 2.7 á 2.8.

La temperatura puede variar entre 17° y 27° C. Puede usarse cualquiera de los volumenómetros, por ej. : la botella de medir densidades, calibrada en cm cúb y fracciones. Llénese el aparato hasta el cero de la escala con bencina. Tómense 100 gram de cemento cernido, secado previamente por exposición de 20 minutos en una plancha metálica á una temperatura de 212° Fah (100° C), y déjesele pasar lentamente á la bencina, teniendo cuidado de que el polvo no se quede sobre el líquido en las paredes del tubo y que el embudo empleado no toque el líquido. La densidad será igual á 100 dividido por el volumen que ha desplazado la bencina en centímetros cúbicos. Esta operación requiere cuidado.

(**3**) **Constancia de volumen** y (**4**) **tiempo de fragua.** La temperatura no debe variar más de 5° ó 6° C alrededor de los 17° C. Para los Portland úsese 20% de agua en peso; para los nat, 30%, y para los puzolanos, 18%. Mézclese bien durante 5 minutos. En láminas de vidrio háganse dos torticas de siete centímetros de diám más ó menos y uno y medio cm ± de grueso en el centro, adelgazándolas hacia las orillas y cúbranse con una tela húmeda. Al cabo del menor tiempo establecido para el comienzo de la fragua, aplíquese una aguja de 2 milímetros de diám con un peso de ¼ lb (113 gramos); si penetra, el cem tiene las condiciones para la fragua inicial exigida. De otra manera la fragua es demasiado rápida. Al final del tiempo requerido para el término de la fragua, úsese la aguja de 1 mm de diám con peso de 1 lb (453 gramos); si no penetra es porque tiene las condiciones necesarias para la fragua requerida. De lo contrario la fragua es muy lenta.

En términos generales, la humedad prolonga ambos tiempos de fragua y se acortan aumentando la temperatura.

Cuando se van á probar los Portland en tiempo húmedo, las muestras deben

---

* En este Informe se entiende por cem Portland el producto obtenido por la calcinación de mezclas íntimas de substancias arcillosas y calcáreas naturales ó artificiales, hasta que se inicia la fusión. Por cem naturales, los fabricados con rocas naturales calcinadas á una temperatura inferior á la de su fusión y luego moliendo el producto; y por puzolanos se entiende el producto obtenido por la molienda de escorias y cal apagada, sin subsiguiente calcinación.

secarse bien antes de agregarles el agua. Se obtendrá bastante uniformidad en la temp si el cuarto de ensayos se mantiene á confortable calor en invierno y si las muestras se conservan á la sombra en un cuarto fresco en verano y bajo un paño húmedo hasta que fraguen. La temp puede variar entre 16 y 27 C, sin afectar el resultado de las observaciones más allá de lo aceptable.

**Prueba á la ebullición**. Colóquense las dos tortas durante 24 horas bajo una tela húmeda. Una de ellas en su plancha de vidrio, se deja en agua durante 28 días; la otra sumérjase en agua á 21°, pero manteniéndola en un soporte sobre el fondo de la vasija; caliéntese el agua gradualmente hasta que hierva, manteniendo el calor por seis horas y luego déjesela enfriar. La torta hervida no debe deformarse, ni presentar grietas de expansión. Si la torta sumergida en agua fría sólo presenta aumento de volumen, se puede emplear el cemento en trabajos ordinarios al aire ó en agua dulce en mezclas pobres; pero si aparecen grietas ó deformaciones, debe rechazarse el cemento.

**Pruebas rápidas** no son recomendables, pero cuando se tiene que hacer una prueba en corto tiempo, la de ebullición es la mejor. No sólo suministra datos en breve tiempo, sino que manifiesta la presencia de ingredientes que pueden producir la desintegración. Por otra parte puede obligar á rechazar un cem que daría buenos resultados en la práctica y que soportaría las pruebas ordinarias después de estar algún tiempo expuesto al aire. El sulfato de cal que ayuda á los cem á soportar la prueba de la ebullición, es un elemento peligroso.

**(5) Las pruebas de tensión** son preferibles á las de flexión ó compresión. Las que se hacen ya mezclado con arena el cem, son las más importantes y deben siempre hacerse; las de cem puro pueden hacerse si hay tiempo.

Un cemento que da un resultado medianamente alto en 7 días y presenta un aumento importante durante los 28 días, es más probable que alcance el máximum de resistencia paulatinamente y lo conserve indefinidamente, que otro cemento que dé en las pruebas una resistencia exagerada á los 7 días, sin presentar ninguno ó muy poco aumento en los 28 días. Usense briquetas de la forma recomendada por la Sociedad Americana de Ingenieros Civiles, que tiene en la sección media de ruptura una pulgada cuadrada (6.45 cm cuad), sostenidas por piezas de metal bien ajustadas. Las pruebas deben hacerse al sacar las briquetas del agua.

**Pruebas de cem puro**. Usense cementos sin cernir. Para cem Portland empléese 20% de agua (en peso), 30% para el natural y 18% para los puzolanos. Colóquese el cemento en una plancha lisa no absorbente; hagásele en el centro un cráter para contener el agua, échesele casi toda el agua de una vez y el resto á medida que la vaya necesitando; mézclese muy bien, moviéndolo con una cuchara y por 5 minutos amásese vigorosamente.

Colóquese el molde de la briqueta sobre una plancha de vidrio ó de pizarra. Llénese el molde con varias capas de cemento como de 6 mm de espesor cada una y apriétese. Désele á cada capa como 30 golpes con un martillo de cobre ó bronce del peso de 1 lb, y de un diámetro de ¾ pulg (19 mm) y cayendo de una altura de ½ pulg (12 mm).

Después de llenar el molde y golpear la última capa, alísese con una paleta, golpéese el molde suavemente en un lado para separarlo de la plancha, quítese ésta y déjese por 24 horas cubierto con una tela húmeda. Luego sáquese la briqueta del molde y sumérjase ésta en agua dulce, que debe ser renovada constantemente ó por lo menos 2 veces por semana durante el tiempo especificado.

**Prueba de tensión con arena**. Para Portland y puzolanos úsese una parte de cem para tres de arena; para los naturales (ó Rosendale), partes iguales. Usese la arena de cuarzo que pase por cedazo n.° 20 y no por el 30.

Después de pesarlos cuidadosamente, mézclense secos el cem y la arena hasta la uniformidad, agréguese el agua como en las pruebas de cem puro y mézclese durante 5 minutos. La mezcla debe amasarse bien.

Para la máxima resistencia en las briquetas de prueba los cem Portland requieren de 11 á 12½ por ciento de agua (en peso de la arena y del cm); los naturales, de 15 á 17, y los puzolanos, de 9 á 10.

Es preferible emplear una máquina que aplique la fuerza gradual y automáticamente, y no una manejada á la mano. La fuerza debe aumentarse á razón de 180 kg por minuto; si se la aplica en una proporción muy distinta á ésta, dará resultados diversos. La mayor resistencia á la tracción, de cada grupo de briquetas hechas al mismo tiempo, debe considerarse como guía de la prueba.

**Otras pruebas** que se recomiendan, aunque se hayan hecho las anteriores. Con cem de marcas conocidas, para apreciar su peso, fineza, su textura y resistencia en las obras, y para saber si el cem es legítimo, si está en buen estado, se hacen

frecuentemente torticas y bolas del cem puro y del mortero probando en ellos con la uña del pulgar la solidez de la fragua, y la resistencia, rompiéndolas con la mano y dejándolas caer sobre una superficie dura. También puede usarse la prueba de la ebullición. Si estas pruebas de tanteo no satisfacen ó dan resultados sospechosos, entonces habrá que hacer los ensayos minuciosos ya explicados.

Se puede rechazar un cem que no tenga las siguientes

### Condiciones oficiales adoptadas en nov. 23 de 1904 por la Junta de Ingenieros de la Gran Bretaña.

**1. Para las consignaciones** de 100 á 250 toneladas deben hacerse las pruebas prácticas y el análisis químico. Para las menores de 100 ton, los fabricantes darán en cada caso, al pedírselos, certificados de que los cem satisfacen aquellas condiciones.

**2. Muestras.** Las muestras deben tomarse del cem, en la fábrica ó ya en el trabajo, á opción del consumidor. Las muestras deben tomarse por lo menos en 12 diversas partes de la masa, mezclarlas y extenderlas, con 7½ cm de espesor por 24 horas, á una temperatura entre 14° y 18° C.

---

*Modificaciones adoptadas por la Sociedad ya citada en sept. de 1908.

Resistencia: Los promedios de las cifras dadas deben tomarse como condición mínima cuando ésta no ha sido especificada.

Cem natural. Omítase la condición de la densidad. Cem Portland. Densidad. Para éstos léase « quemados á un rojo bajo » donde dice « secados á 100°C »

Pérdida de peso al fuego no más de 4 0/0.

**Condiciones oficiales adoptadas en nov. 23 de 1904 por la Junta de Ingenieros de la Gran Bretaña.** (Continuación.)

**3. Fineza.**

| Mallas por pulg lineal. | Mallas por pulg cuad. | Alambre, diám en pulgs. | Residuo máximo, |
|---|---|---|---|
| 76 | 5776 | .0044 | 5.0% |
| 180 | 32400 | .0018 | 22.5% |
| por centím lineal. | por centím cuad. | diám en mm. | |
| 30.4 | 924 | .11 | 5.0% |
| 72 | 5184 | .045 | 22.5% |

La tela de alambre no debe ser cruzada.

**4. Resistencia á la tracción.**

El cuarto de ensayos debe estar á una temperatura de 14° á 18° C.

El agua dulce, renovarse cada 7 días; y su temperatura de 14° á 18° C. La pasta debe ser suave, de fácil amasijo, que salga de la cuchara ó paleta en una masa compacta y nítida.

Debe llenarse el molde de la probeta sin golpearla, dejándolas descansar en una plancha de hierro hasta que el cemento fragüe. Las probetas deben quedar por 24 horas en una atmósfera húmeda y luego en agua hasta que se vayan á romper. Garfios; véase fig. 1.

(*N. del T.* R=15 mm; $r$ = 10 mm; W = 44 mm; $w$= ancho= espesor = 25 mm; H=76 mm; $h$=51 mm. Las figuras están en una escala de 2/5).

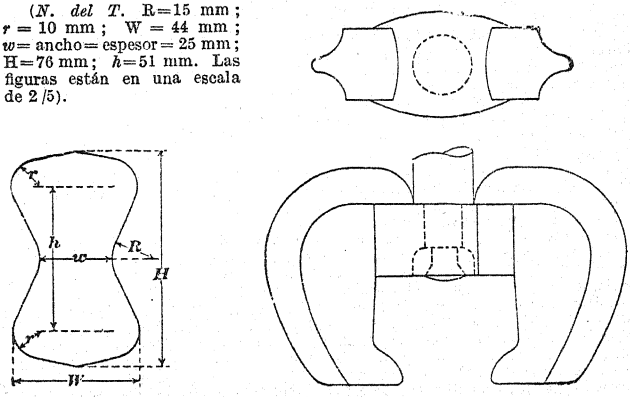

**Fig. 1.** Probeta y garfios.

*Carga;* comiéncese en 0; y agréguensele como 46 kg cada 12 segundos.

Ensayo de cem puro. Seis probetas en 7 días y 6 en 28 días. Se acepta el resultado medio de las 6 como la medida de la resistencia. Siete días no menos de 28 kg por cm cuad; á los 28 días no menos de 35 kg por cm cuad.

Cuando la prueba á los 7 días está entre :

| Kilg por cm cuad. | El aumento entre 7 y 28 días no debe ser menor de |
|---|---|
| 28.02 y 31.60 | 25% |
| 31.60 y 35.20 | 20% |
| 35.20 y 38.70 | 15% |
| 38.70 y más | 10% |

Prueba con la arena. Por peso se mezclan 1 de cem y 3 de arena normal, lavada y seca. La arena debe pasar por un tamiz n.° 20 de alambres de .4 de milímetro y que no pase por el tamiz n.° 30 de alambre de .28 mm. Mézclese y humedézcase sin exceso de agua. A los 7 días 8.44 kg por cm cuad; á los 28 días 15.82 kg. Aumento de 7 á 28 días no menos de 20%.

**Condiciones oficiales adoptadas en nov. 23 de 1904 por la Junta de Ingenieros de la Gran Bretaña.** (Continuación.)

| | Tiempo en minutos máx | mínimo. |
|---|---|---|
| **5. Fragua.** | | |
| Rápida | 30 | 10 |
| Mediana | 120 | 30 |
| Lenta | 300 | 120 |

La fragua se ha efectuado cuando la aguja con 1.13 kg de peso, teniendo la punta chata y de 1.6 mm en cuadro, no deja marca.

**6. Variación de volumen.** Le Chatelier: La expansión no debe exceder de 12 milímetros después de 24 horas al aire; 6 mm después de 7 días.

**7. Densidad.** No debe ser menor de 3.15 al tomar las muestras en fábrica; no menos de 3.10 al entregarlo al consumidor.

**8. Análisis.** Agua no más de 2%, ya sea agregada ó absorbida del aire.

**Sulfato de calcio**: no más de 2% del peso del cem, calculado como sulf de calcio anhídrico.

**Cal**: no más de la necesaria para saturar el sílice y la alúmina.

Residuo insoluble: no más de 1.5%. **Magnesia**: no más de 3%. *Anhidro sulfúrico*: no más de 2.5%.

## Pruebas.
## Sociedad americana de ingenieros civiles.

Extracto del Informe de la Comisión sobre pruebas uniformes de cem, de enero de 1903, y revisado en enero de 1904 y enero de 1908.

**1. La elección de las muestras** queda á discreción del ingeniero. El número de muestras y la cantidad que debe tomarse de cada lote, dependen de la importancia de la obra, del número de ensayos que se piensen hacer y de las facilidades para hacerlas. Cuando sea posible tómese la muestra para probar de cada 10 barriles uno. Las muestras aisladas pueden mezclarse y probar su promedio; pero cuando sea posible pruébense separadamente.

**2. El cem en barril** debe probarse tomando por un agujero el cem á mitad ó en la tapa del barril. El cem, en sacos, se debe probar de la superficie hacia el centro.

**3. Ciérnanse las muestras** en tamiz n.° 20.

**4. El análisis químico** puede demostrar la adulteración en cem ricos en materia inerte; pero esto no es concluyente para apreciar la calidad. La Comisión recomienda el método propuesto por la « Comisión de uniformidad, etc., de la Sociedad de Industria Química de la sección de Nueva York ».

**5. Prueba de la densidad.** Se recomienda el método Le Chatelier, fig. 1 (pág. 1281). El frasco, D, de 120 cm cúb; cuello de unos 9 mm de diámetro y 20 cm de largo, con un ensanche, C, de 20 cm cúb entre F y E. El cuello está graduado en .1 de cm cúb de F hacia arriba. El embudo, B, entra en el frasco y llega hasta F. Usese bencina (62° Baumé) ó kerosene libre de agua. Durante la operación, para evitar cambios de temperatura en este líquido, se mantiene el frasco dentro del agua en un depósito. Hay dos métodos, que son:

(*a*) Llénese el frasco hasta la marca E. Pésense 64 gramos de polvo de cem á la temp del líquido. Introdúzcase gradualmente el polvo de cem por el embudo B, hasta que el líquido suba á la marca F. Entonces llámese *w* á los 64 grms, menos lo que pese el polvo no empleado y la densidad será *w* /20.

(*b*) Llénese con el líquido hasta la marca E como se hizo antes. Échense todos los 64 grms de cem y véase á qué división del cuello llega el líquido; lo que marque esta división más 20 cc es el volumen *v* de los 64 gramos de cem y su densidad $= \frac{64}{v}$.

**6. Fineza.** Los tamices deben ser circulares de unos 20 cm de diám, 6 cm de alto, con una profundidad libre de 5 cm y con tapa. Estos tamices son de tela de alambre.

N.° 100, 96 á 100 mallas por pulg lineal (38 á 40 por cm); diám del alambre .0045 pulg (.11 mm);

N.° 200, 188 á 200 mallas por pulg lineal (75 á 80 por cm); diám = .0024 = .06 mm.

Empléense 50 á 100 gramos de cem secado á 100° C. Debe preferirse tamizar á mano. Usese el n.° 200 durante un minuto y dando 200 vaivenes por minuto, no pasa más de $^4/_{10}$%. Pésese el residuo y hágase lo mismo con el n.° 100. Una pequeña cantidad de municiones gruesas de acero ayuda la operación.

**Pruebas. Soc amer de ing civ.** (Continuación.)

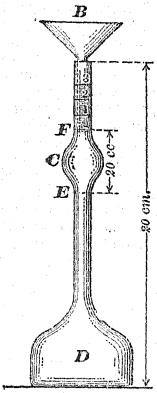

**Fig 1.**
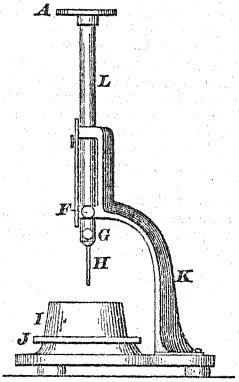
Frasco de densidad.



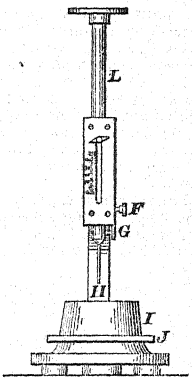


**Fig 2.**
Aguja de Vicat.

I, anillo de goma; J, plancha de vidrio; H, aguja Vicat; L, cilindro ó barra que resbala; F, tornillo que puede comprimirla.

**7. Consistencia normal.** El percentaje de agua empleado para hacer las pastas en las pruebas de resistencia, variación de volumen y fragua, afecta en alto grado los resultados. La consistencia normal se determina así: La cantidad de cem que se va á usar en lo sucesivo en cada montón para hacer las probetas, y que no debe ser menor de 500 gramos, se amasa en una pasta (como se indica más adelante en el capítulo «Mezcla», § 12), haciendo con ésta rápidamente una bola, y pasándola de mano á mano seis veces, á 15 cm de distancia. Luego se fuerza la bola en la abertura del aparato de la aguja Vicat dentro del anillo de caucho (7 cm de diám por 4 cm hondo), se la alisa por debajo y se coloca en una lámina de vidrio. Se pule la parte superior con una cuchara y se la pone en contacto con la punta de la aguja dejando descender el cilindro. La pasta será de consistencia normal si la aguja penetra un centímetro.

**8. Fragua.** Esta se inicia cuando la aguja de Vicat de 1 mm de diám, con peso de 300 gramos, se detiene á más ó menos 5 mm de la plancha de vidrio, y termina cuando la aguja no penetra en la masa. Las muestras de prueba deben mantenerse húmedas durante aquélla, en una caja ó armario húmedo ó colocadas sobre el agua en un soporte y cubiertas con una tela húmeda que no las toque. Manténgase la aguja limpia. El tiempo de fragua cambia mucho con la temperatura del agua que se le pone, la temperatura y humedad del aire, por la proporción del agua empleada y por el trajín con que se trabaje la pasta al moldearla.

**9. Arena normal.** No es aceptable el cuarzo triturado, «especialmente á causa de la gran proporción de los vacíos, la dificultad de compactarlo en los moldes y su poca uniformidad». La arena debe pasar por el tamiz n.º 20, cuyos alambres tengan un diám=á la mitad del espacio que los separa; no menos del 99% debe quedarse en un tamiz análogo n.º 30; después de darle un minuto de continuo zarandeo á una muestra de 500 gramos.

**10. Probetas** normales. (Véase fig. 3.)

**11. Moldes.** Deben ser de cobre, ú otro metal no corrosible, cuyas paredes sean bastante fuertes para soportar el apelmazamiento. Se recomiendan los moldes en serie, fig. 4, por requerir más mortero; además, se obtiene mayor uniformidad. Los moldes se limpian, antes de usarlos, con una tela aceitada.

**12. Operación de mezclar.** Las proporciones mencionadas son por peso y la cantidad de agua es un tanto % del material seco. Se recomienda usar el sistema

## Pruebas. Soc amer de ing civ. (Continuación.)

métrico. La temperatura del cuarto y el agua para la mezcla deben ser lo más próximas posible á 21° C. La arena y el cem se mezclan secos, y esta operación debe hacerse en una superficie no absorbente, prefiriendo el vidrio. La cantidad de material que se mezcla de una vez, depende del número de piezas de prueba que se van á hacer; las mezclas deben hacerse de 1,000 grms más ó menos, sobre todo cuando se hacen á mano. Se recomienda la mezcla y el moldeo á mano. Pesado el material y colocado en la plancha, se le forma un cráter en el centro, en el que se echa el agua limpia, y el material de la orilla se va sucesivamente mezclando con el agua. Al quedar absorbida el agua, se completa la operación amasando vigorosamente la mezcla durante 1½ minutos. Pueden protegerse las manos con guantes de caucho.

Se llenan los moldes al concluir la mezcla, se comprime fuertemente el material con los dedos y se alisa la capa superior con una paleta sin presión á martillo; la paleta, al barrer el exceso de material, debe correr al contacto del molde y ejercer una ligera presión sobre el material. Inviértase el molde y repítase la operación por el otro lado. Pésense las briquetas antes de sumergirlas en agua ó al sacarlas de la caja húmeda y rechácense las que varían en más del 3% del peso medio.

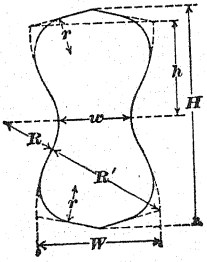

**Fig. 3.** Probeta.

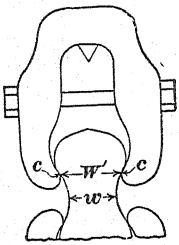

**Fig. 5.** Garfio.

Fig. 3. H=76 mm; $h$=33 mm; R=19 mm; $r$=13 mm; W=44 mm; $w$=ancho=espesor=25 mm.
La línea de puntos indica la forma recomendada últimamente.
Fig. 5. W'=31.7 mm; $w$=ancho=espesor=25 mm; $c$=contacto con la probeta=1.6 cm cuad.

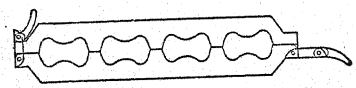

**Fig. 4.** Serie de moldes.

**13. Caja húmeda.** Ésta se hace de una piedra porosa como la esteatita, ó de pizarra, ó de metal, y éste forrado en fieltro mantenido siempre húmedo; el fondo debe contener agua y los lados provistos de apoyos para sostener las láminas angostas de vidrio que sustentan las probetas. Cuando no se dispone de una caja, se emplea un paño siempre húmedo que envuelva las probetas sin tocarlas.

**14. Inmersión.** Después de 24 horas de exposición al aire húmedo, las piezas de prueba deben sumergirse por mayor tiempo en agua lo más próxima á 21° C; se pueden conservar en estanques ó depósitos no corrosibles.

**15. Resistencia á la tracción.** Para esta prueba se recomiendan los garfios enterizos de metal, fig. 5. No debe haber cojines entre el garfio y la probeta, debe haber buen contacto. Las probetas deben ensayarse al sacarlas del agua colocándolas con cuidado en el garfio, para impedir tracciones transversales, y apliquese el peso á razón de 272 kg más ó menos por minuto. El promedio de los resultados de cada grupo de probetas ensayadas será el dato de la experiencia, excluyendo alguna que dé un resultado tan discordante que sea visiblemente erróneo.

**Pruebas. Soc amer de ing .civ.** (Continuación.)

**16. Constancia de volumen.** « En el estado actual de nuestros conocimientos no se puede rechazar un cem simplemente porque no satisface en las pruebas rápidas indicadas más abajo, ni aceptarlo como bueno por la sola razón de haber correspondido á ellas. »

Háganse tortas de consistencia normal (§ 7), de unos 7½ cm de diám y 1¼ de espesor en el centro, y adelgazándolo hacia las orillas, sobre láminas limpias de vidrio de 10 cm por lado; expóngase por 24 horas al aire húmedo antes de la prueba.

(1) Prueba normal. Sumérjase una de las tortas en agua, lo más próxima posible á 21° C, y la otra al aire á la temperatura ordinaria; y obsérvense ambas de vez en cuando por 28 días.

(2) Prueba rápida. Se expone una de las tortas á los vapores de agua hirviendo, en una vasija á medio tapar, por 5 horas.

Las tortas deben conservarse intactas y duras sin indicios de grietas, quebradura ó deformación. Se puede descubrir cualquier curvatura aplicando una arista recta á la superficie que tocaba el vidrio.

## ARENA*

### Composición.

**1.** La arena * que se usa en los morteros está compuesta generalmente de granos de **cuarzo (sílice)**, con algunas impurezas, en su mayor parte granos de minerales silícios. Para probar los cem en los laboratorios se emplea cuarzo triturado ó arena natural normal. (Véanse las especificaciones anteriores sobre el cem.)

**2.** La sílice del cuarzo en la arena, no sufre alteración química en el mortero; pero, el empleo de la arena disminuyendo la cantidad del cem requerido, reduce el costo de la obra. (Véanse la observaciones sobre resistencia, pág. 1292.

## TAMAÑO DE LOS GRANOS

**3. Tamizada.** La arena y el granzón se tamizan generalmente en un cedazo inclinado y fijo al que se lleva el material, por transporte mecánico ó paleado á mano, ó por medio de un cedazo giratorio cilíndrico ó prismástico al cual se va llevando el material.

**4. Cuarteo.** Para obtener un verdadero promedio de un montón de arena, granzón ó piedra, es útil el método de cuarteo. Se van tomando paladas de distintas partes del montón, se mezclan y se esparcen en círculo; este círculo se divide en 4 partes como una torta. Una de estas partes se separa del resto, se mezcla muy bien, se vuelve á esparcir y á dividir como antes, repitiendo esto hasta que la cantidad se reduce á lo necesario para la muestra.

### Análisis mecánico.

**5.** El análisis mecánico de las arenas consiste en determinar en una arena, granzón ó cascajo dados, la proporción de granos de diversos tamaños. Esto se logra por medio de tamices. A veces en las piedras trituradas basta escogerlos con la mano.

**6.** La fig. 1 sirve para ilustrar el examen de un granzón y una arena, hechos por Allen Hazen, de Massáchusets. Para representar ambos exámenes en un mismo diagrama hemos usado diferentes escalas para los diversos diáms de los dos materiales.

---

* **Por arena y granzón** se entiende una mezcla de partículas minerales separadas por espacios llenos de aire ó de agua, ó de ambos. Por tanto, el volumen de una cantidad de arena ó granzón es el ocupado por las partículas sólidas y por el aire ó agua entre ellas.

**7.** En la fig. 1 el diagrama demuestra, para los dos materiales representados, que :

para la arena 10% era de granos menores y el 90% mayores de .0055 mm
— el granzón 10% — — — 90% — 34.5 —

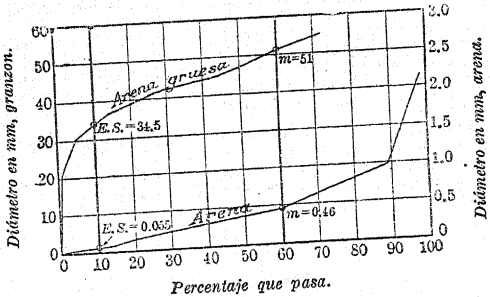

Fig. 1.

**8. El tamaño efectivo** (E S en el diagrama) de una arena ó de un granzón es aquel bajo el cual sólo hay un 10% (en peso) de granos en la masa y el 90% restantes son iguales ó mayores que el tamaño ó diám dicho. Así lo aprecia el Sr. Hazen, de Boston.

## Coeficiente de uniformidad.

**9. Coeficiente de uniformidad** (« c. u. ») De la misma manera sea $m$=al diámetro del grano bajo cuyo tamaño componen el 60% del peso de la masa siendo el 40% mayor. En la fig. 1 tenemos para la arena $m$=.46 mm; para el granzón $m$=51.00 mm.

El coeficiente de uniformidad es $m \div$ el tamaño efectivo; es decir, $m \div$ E S; lo que da para la arena, c. u. = .46 / .055 = 8.4; para el granzón, c. u. = 51.00 / 34.5 = 1.48.

**10.** Con $m$=E S el coeficiente de uniformidad (c. u.) tendrá el menor valor posible ó sea 1.

**11.** En los bancos de arena, el tamaño efectivo (E S) no varía mucho, por lo que el coeficiente de uniformidad, c. u. = $m$/E S, varía aproximadamente con $m$, diámetro éste superior al 60% del resto de los granos y sirve para indicar el grosor de la arena y lo que se aleja de la uniformidad.

## Método Feret.

**12.** El Sr. R. Feret (Anales de puentes y calzadas, 1892, 2.º semestre) ha hecho cuidadosos ensayos sobre los efectos de la fineza de la arena y de la mezcla de diferentes grados de fineza, sobre su densidad, etc., y sobre las diversas cualidades del mortero. Divide las arenas en los 3 grados de fineza siguientes :

Gruesa, $g$, más de 5.0 mm diám = 4 mallas /cm cuad = 5 mallas /pulg lineal.
Mediana, $m$, — 2.0 — — = 36 — / — = 15 — / — —
Fina, $f$, — .5 — — = 324 — / — = 46 — / — —

Los granos gruesos son detenidos en 2 mm diám; los « medianos » en .5 mm.

**13.** Los resultados obtenidos en determinado caso con las diferentes mezclas de estos 3 grados de fineza se ven demostrados en la fig. 2, la que se asemeja á los diagramas usados para las ligas de 3 metales.

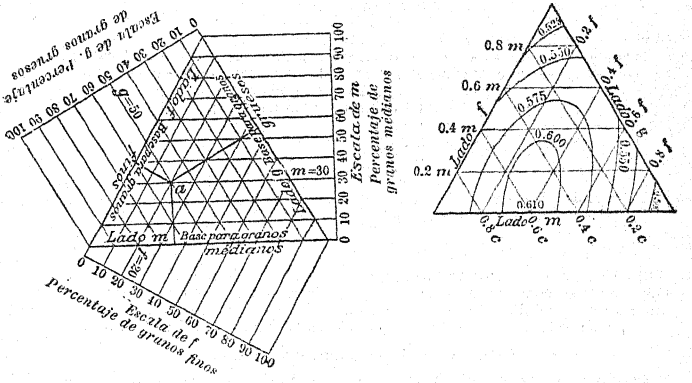
**14.** Después que se ha analizado una mezcla dada, y determinados así los percentajes de sus tres grados de fineza, se fija en el triángulo equilátero un punto situado de tal manera en él, que sus distancias á los lados sean las siguientes :

distancia al lado $g$ (arena gruesa ) = percentaje de granos gruesos;
— — $m$ ( — mediana) = — — medianos;
— — $f$ ( — fina ) = — — finos.

**15.** La fijación del punto y la medida de las distancias se facilita por medio de las paralelas á los tres lados.

**16.** Así el punto *a*, fig. 2, representa una arena que tiene 20% de granos finos, 30% medianos y 50% gruesos, como se ve en las distancias allí determinadas.

**17.** Cuando se ha hecho una serie de experimentos sobre cualquier cualidad dada (como densidad, porosidad, etc., para la cual son idénticas las otras condiciones) de la arena ó mortero, afectada por las diferencias de las mezclas de las 3 finezas, se fijarán los puntos que la midan en los lugares que les corresponda en el diseño alrededor del punto representativo de la mezcla y se trazarán **líneas de contorno** por los puntos que indican el mismo resultado sobre la cualidad que se estudia. Cada



una de esas líneas indica, por consiguiente, las diferentes mezclas que dan el valor (de la densidad, porosidad, etc.) que dicha línea representa.

**18.** Así, en la fig. 3, las cuatro líneas de contorno y el punto (.610) representan cinco mezclas de arena gruesa, fina y media que tienen las densidades de (véase § 20) .525, .550, .575, .600, .610, respectivamente.

## Densidad.

**19. Peso de la unidad de volumen.** El cuarzo sólido pesa ± 165 lbs por pie cúb = 2.643 grams por cm cúb; su densidad = de 2.64 á 2.67.

**20.** En mecánica (pág. 354, art. 14 *a*) **se define la densidad** por la masa bajo la unidad de volumen. En la arena las partes sólidas tienen prácticamente la misma densidad. Por tanto, en una arena dada, la densidad es la fracción del volumen de la parte exclusivamente sólida en la unidad de volumen de la arena, ó la relación entre la parte sólida y el volumen total. Esta relación se llama á veces el volumen real. Así, en la unidad de volumen de la arena, « densidad » = 1—volumen de los vacíos.

**21.** Mientras mayor es la densidad de una arena, menor cantidad de cemento requiere una cantidad dada de mortero.

**22. El peso por unidad de volumen** de una arena, de determinada densidad, varía directamente con esta densidad, y ésta, á su vez, depende de la forma de los granos, de la escala ó proporción de sus tamaños, de la compactación que se logre por sacudida, presión, golpe, etc., y de la sequedad.

## Efectos de la humedad.

**23. Los efectos de la humedad** sobre el volumen de una cantidad dada de arena varían con el volumen de aire introducido, con la cantidad de agua y con la forma de los granos. (Véase 29 á 31.)

**24.** No es posible medir el volumen de **aire introducido** y su presencia altera todas las observaciones. Cuando se dejan caer los granos de arena, uno por uno, en

agua, la mayor parte del aire que rodea los granos se queda en la atmósfera; pero, cuando se arroja la arena dentro del agua, en masa, ó cuando se remueve la arena húmeda ó mojada, arrastra una considerable y desconocida cantidad de aire que queda adherida al grano.

**25.** En la arena húmeda el volumen total ó « absoluto » de los vacíos está generalmente ocupado parte por el agua y parte por el aire.

**26.** Dentro de cierto límite, la **humedad** aumenta la adhesión entre los granos de la arena, se opone á que se deslicen unos sobre otros y estorba, por consiguiente, la compactación por contacto; pero, salvado aquel límite, obra como un lubricante y la facilita. (Véase 24-25.)

**27.** Sean

$V$ = volumen en litros de cuarzo seco en 1 litro de arena;
$v$ = — — — de los vacíos en 1 — — $V+v=1$ litro;
$W$ = peso en kg de 1 litro de cuarzo sólido = 2.643;
$w$ = — — de 1 — de la arena (seca ó húmeda) como sea el caso;
$d$ = — — de cuarzo seco en 1 lit de la arena (en arena seca $d=w$);
P = — — del agua agregada á 1 kg de arena seca;
= — — — en $(1+P)$ kg de arena húmeda;
$p$ = — — — en 1 kg — —
$m$ = — — — en 1 litro — —

Tenemos que $\frac{p}{P} = \frac{1}{(1+P)}$; y $p = \frac{P}{(1+P)}$;

$m = wp$; $d = w - wp = w(1-p)$;
$V = (w - wp) \div W = d/2.643$; $v = (1-V) = 1 - d/2.643$;
$w = W\frac{1-v}{1-p} = W\frac{V}{1-p}$.

**28. El grado de humedad** (kgs de agua en 1 kg de arena) se obtiene calculando un peso conocido de arena, á una temperatura no menor de 100° C hasta que no cese la pérdida de peso, y tomando nota del peso. Luego :

$p$ = pérdida de peso ÷ por el peso original de la porción calentada.

## Influencia de la forma y el tamaño.

**29. Granos esféricos.** Amontonando del modo más compacto posible un número de esferas de diámetro uniforme, D, la relación entre el volumen sólido y el volumen total es $\frac{\pi\sqrt{2}}{6} = \pm .74$; y los vacíos ($\pm 0.26 \times$ el volumen total) son de dos tamaños y tales que en ellos caben esferas de diáms = más ó menos .41 D y .22 D.

**30. Efecto de la graduación de tamaños.** La proporción de los vacíos se puede reducir indefinidamente mezclando á los granos originales otros más y más pequeños, ó más y más grandes, en la debida proporción, cada partícula irá ocupando los espacios vacíos de las partículas más gruesas. Por consiguiente, con partículas esféricas los vacíos son mayores y menor el peso por unidad de volumen cuando los granos son del mismo tamaño. Esto se aplica de un modo análogo á partículas no esféricas.

## Otras propiedades.

**31. Prueba de turbiedad á causa del fango.** Sepárese el fango de una cantidad considerable de arena y hágase una muestra especial que lleve la mayor cantidad relativa de fango permitido en la arena. En una vasija graduada colóquese dentro de determinada cantidad de agua limpia una porción conocida de arena. Agítese la vasija hasta lavar la muestra completamente. Insértese un alfiler horizontalmente en el extremo de una varilla, introdúzcase esta punta dentro de la vasija, bajándola hasta que deje de verse el alfiler dentro del líquido, y anótese la profundidad de aquél midiéndola en la graduación del vaso. Háganse varias pruebas y calcúlese la profundidad media en que deja de verse el alfiler. Si en las pruebas de las muestras el alfiler deja de verse á mayor altura que la normal, es porque la arena contiene más fango que el permitido y viceversa. (W. J. Dougias, E. N., dic. 20/1906, pág. 648.)

**32. La presencia de arcilla y barro en la arena** se puede comprobar frotando la arena húmeda en la mano y observando la mancha que deja, ó mezclándola con agua limpia para observar cuánto la ensucia.

**33. Lavado.** La arena sucia se puede lavar en un lavadero especialmente cons-

truído, ó en un depósito, con una manga de agua, ahogando la arena de manera que las impurezas más livianas floten y se derramen.

**34.** El lavado puede arrastrar las partículas más finas de una arena bien proporcionada, dejándola menos densa; sería conveniente ensayar una pequeña cantidad lavada y otra sin lavar, antes de lavarla para usarla. (Jas. C. Hain, E. R., enero 28/905.)

**35.** La bondad de una arena y la agudeza de sus granos se aprecia por el sonido que produce al friccionar con la mano unos granos contra otros, ú observarlos con una lente.

## MORTERO*

### Elementos.

**1. El mortero de cemento** consiste en cemento mezclado con agua, con ó sin materiales inertes granulados, como arena, granzón, cascajo, piedras ó escorias trituradas. Sin arena, etc., se llama **mortero puro** ó **pasta de cemento.**

**Cantidad de mortero requerida para la unidad de mampostería** **.

| Especies de mamposterías. | Por unidad de volumen, sea yarda ó metro cúbico. Mín. | Máx. |
|---|---|---|
| Mampostería de 18″=45 cm, juntas ¼″=6 mm | .03 | .04 |
| — de 12″=30 cm, — ¼″=6 mm | .06 | .08 |
| — de ladrillo (ladrillos de=21×10×5½ cm) : | | |
| — con juntas de 3 mm | .10 | .15 |
| — — de 9 á 6 mm | .25 | .35 |
| — — de 15 á 12 mm | .35 | .40 |
| — ordinaria de piedra pequeña en bruto | .33 | .40 |
| — — — grandes labradas toscamente á martillo | .20 | .30 |
| — — — cuadradas, muro de 45 cm y juntas de 20 mm | .12 | .15 |
| La misma anterior, pero de 30 cm de grueso | .20 | .25 |

**2. Efecto de la calcinación y la mojada subsiguiente.** Los materiales de que se hace el cem son mezclas inertes ó estables, que permanecen prácticamente sin cambiar en las condiciones ordinarias; pero, cuando se calcinan, los elementos calcáreos se someten á altas temperaturas, solos ó mezclados con las materias arcillosas, formándose entonces combinaciones relativamente instables, las cuales vuelven á convertirse en inertes cuando sus partículas se ponen en íntimo contacto al mezclarlas con agua, y ésta misma entra á formar nuevas combinaciones. La mezcla fragua pronto (pierde su plasticidad) y luego, por consiguiente, comienza á solidificarse y endurecerse. (Véase 8, Cemento, pág. 1269)

**3.** En el proceso de cristalización la alúmina parece que obra principalmente **como fundente** fomentando la formación del silicato de cal, de lo que depende el buen resultado de la operación. El óxido de hierro que se encuentra generalmente presente parece ejercer tan bien como la alúmina la acción fundente, requiriendo menor temperatura para la calcinación.

**4. La proporción de arena** que se debe emplear en un caso dado no se puede fijar con exactitud sin determinar la proporción entre sus vacíos y el volumen total; pero generalmente un buen cem Portland soporta dos ó tres veces su propio volumen de arena; los naturales de 1½ á 2 vol.

**5.** Cantidades **aproximadas** de cem Portland y arena suelta por metro cúbico de mortero :

| | Puro | 1:1 | 1:2 | 1:3 | 1:4 | 1:5 | 1:6 |
|---|---|---|---|---|---|---|---|
| Barriles de cem.... | 10.4 | 6 | 4 | 3 | 2.33 | 2 | 1.70 |
| Metros cúb de arena | 0 | .845 | 1.03 | 1.26 | 1.33 | 1.38 | 1.43 |

* Como la fuerza, permeabilidad, etc., de un hormigón de cemento depende sobre todo de que el mortero tenga aquellas condiciones, nos ocupamos en el capítulo « Mortero » de muchas de las propiedades tratadas en el capítulo « Hormigón de cemento ».

** Tomado de un tratado de « mamposterías » por el prof. Iro O. Baker. Nueva York, 1907.

## Cemento en el mortero.

(Véase también CEMENTO, pág. 1268.)

**6.** Debido al bajo precio con que hoy se fabrican los cem y la superioridad de los morteros hechos con ellos, éstos, recientemente y en gran parte, han reemplazado los morteros de cal, aun para trabajos ordinarios.

**7.** Al escoger un cemento, la **reputación** que haya adquirido en muchos años de prueba tiene más valor que el resultado de unas pocas pruebas; pero éstas tienen su valor para la exclusión de algún lote de inferior calidad.

**8.** Los cementos superiores resultan generalmente económicos aun costando más, pues soportan mayores cantidades de materiales baratos, como la arena, granzón y piedra picada.

**9. Cal libre.** El cem puede contener cal « libre » (sin combinar) como consecuencia de (1) insuficiente manipulación del material bruto, (2) de insuficiente calcinación, (3) de un exceso de carbonato de cal ($CaCO_3$) en la materia prima, ó (4) de adulteración después de la quema y molida.

**10.** Esta cal puede presentarse como cal viva, CaO, ó como cal apagada, $Ca(OH)_2$; cualquiera de las dos puede ser **lavada** (la CaO se convierte primero en $Ca(OH)_2$ por infiltración de agua. Esto, naturalmente, debilita el cem.

**11. La cal apagada** no influye en el proceso de endurecimiento, sino que permanece como material inerte de relleno.

**12. La cal viva** se apaga absorbiendo el agua empleada en la mezcla; y cuando se ha hecho la quema á alta temperatura, se demora la **apagada**. Si tiene lugar durante la fragua del cem, la hinchazón de la cal debilita á aquél haciéndolo poroso. Si la apagada se retarda hasta después del endurecimiento, y si la fuerza de expansión es bastante, se desintegra el cem.

**13. El exceso de cal** demora la fragua y daña la constancia de vol.

**14. Magnesia libre.** Hay mucha inseguridad respecto á los efectos de la magnesia libre en diferentes proporciones, sobre el cem. Como la cal, se expande al humedecerse, pero con mucha más lentitud, y su presencia, por tanto, permanece sin sospecharse mucho más tiempo. La **dolomita**, ó sea la caliza magnésica, contiene un 45% de magnesia. Antes 1.5% de magn libre en el cemento se consideraba peligroso; hoy se cree generalmente que más de 3 á 5% lo debilita y que 8% ó más lo agrieta. En cualquier proporción, es probablemente rechazable, por lo menos porque ocupa el puesto de la cal que es más útil.

## La arena en el mortero.

(Véase ARENA, pág. 1283.)

**15.** La calidad de los hormigones de cemento depende del vigor del mortero, y éste, á su vez, principalmente de las condiciones de la arena.

**16.** Para un peso dado, la mejor arena es la que produce el más pequeño volumen de mortero plástico.

**17. Peso.** Entre dos arenas de una misma especie, la más densa tiene naturalmente el menor vol de vacíos.

**18. Fineza.** Una arena fina bien surtida en el tamaño de sus granos y por tanto densa, puede producir un mortero mejor que otra gruesa con granos más uniformes y por consiguiente menos densa.

**19. La extrema fineza** impide la penetración de la pasta entre los granos y demora la fragua.

**20.** Los morteros de arena fina, aunque menos permeables que los de arena gruesa, se prestan más á la acción del **agua salada**.

**21. Contracción.** Los morteros de arena gruesa se contraen menos que los de arena fina.

**22. Agudeza de los granos.** Se ha acostumbrado insistir en esta cualidad de las arenas empleadas en los morteros, debido probablemente á la impresión de que los granos agudos se unen mejor al cem ó de que la tal agudeza es indicio de que la arena está pura; pero esto es dudoso. Las arenas de grano redondo se usan generalmente con satisfactorios resultados, y las pruebas de laboratorio indican en general que las de granos agudos no poseen ninguna notable superioridad. La redondez de los granos facilita el empaque y aumenta su densidad.

**23.** La Comisión de O. P. de Puerto Rico encontró en ensayos de morteros (de 1 : 2) 25% más de resistencia en los de arena lavada que en los de arena no lavada. La arena que contiene mucha materia extraña debe probarse antes de aceptarla.

**24.** En general, al juzgar sobre **los méritos relativos de la arena y de las cerniduras** (*screenings*), el fallo parece favorecer á éstas (véase « Experiencias »);

pero las opiniones divergen. La hidraulicidad del polvo en las cerniduras puede aumentar la fuerza del mortero.

**25.** Harry Taylor, capitán de ingenieros del ejército de los E. U., ensayó 1,650 probetas de morteros de 1 : 3, 1 : 4, 1 : 5 en 1, 3, 6 y 12 meses, de cuarzo normal triturado, arenas y **polvo de la trituración**; estos últimos produjeron probetas de 2.3 de mayor fuerza que las de arena y 72% más fuerte que las de cuarzo. Las de 1 : 5 hechas con polvo de piedra resultaron más fuertes que las de 1 : 3 de cuarzo.

**26.** El Sr. G. J. Griesenauer, de Chicago, hizo las siguientes 225 pruebas:

**Cerniduras de piedra caliza** 1 : 3 pasadas por cedazos n.° 12 y detenidas en el n.° 40 dieron un promedio de 74% superior á las arenas de pozos secos, 1 : 3 empleando todos los tamaños resultó 115% superior. Los morteros de 1 : 6 de cerniduras dieron 23% más fuerza que los de 1 : 3 de arena, **las cerniduras** de granzón no dieron mejor resultado que la arena.

**27.** En los caminos de Maryland las probetas hechas con **cerniduras de piedra** dieron de 34 á 62% más resistencia que las hechas con arena del río Potomac.

## La cal en los morteros.

**28.** El reemplazo de 10 á 20% de pasta de cal por igual volumen de pasta de cemento reduce el costo del mortero, y retarda un poco la fragua sin disminuir considerablemente su fuerza. Mayores cantidades lo debilitan. (Construcciones de mampostería, por Baker.)

**29.** Feret encontró que el efecto de la cal depende de la riqueza en cem del mortero. En morteros de 1 : 4 el aumento de 4 á 5% de cal apagada seca aumenta la fuerza; mientras que en morteros de cem de 1 : 1.25 disminuye la fuerza al agregarle cal. (« Chimie Appliquée », 1897, pág. 481.)

## Arcilla en el mortero.

**30.** Los ensayos de laboratorio indican que **pequeños aumentos de arcilla** aumentan en vez de disminuir la fuerza del mortero, y reducen su permeabilidad; pero, en la práctica, las partículas de arcilla conservan su compacticidad y forman como terrones de poca cohesión.

**31.** Las condiciones alcanzadas en los laboratorios en cuanto á sequedad, pulverización, etc., no se logran en la práctica.

**32.** Cuando la arena contiene arcilla no es posible una mezcla perfecta.

**33.** La arcilla y sus análogos producen más inconvenientes en las mezclas secas que en las húmedas.

## Consistencia.

**34. Resistencia relativa de los morteros secos y húmedos, 1 : 1.** Más de 5,000 ensayos hechos por Alfred Noble. Tomando como 100 á la resistencia del mortero seco.

| | Cem Portland. | | | | Cem natural. | | | |
|---|---|---|---|---|---|---|---|---|
| Edad | 30 días | 3 meses | 6 meses | 1 año | 30 días | 3 meses | 6 meses | 1 año. |
| Mortero seco..... | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 |
| Medio espeso..... | 97 | 94 | 97 | 97 | 78 | 89 | 95 | 90 |
| Húmedo..... | 90 | 92 | 91 | 95 | 63 | 77 | 86 | 82 |

**35.** Usese el hormigón de cem (concreto) seco, cuando se vaya á someter inmediatamente á fuertes cargas. Los ensayos demuestran que los húmedos y los secos alcanzan la misma resistencia al año.

**36.** Los húmedos se adhieren mejor á las obras viejas que los secos. El exceso de agua aumenta la lechosidad y la eflorescencia.

**37. Regla para el percentaje, W, del agua.** (Cost Data, pág. 266, por H. P. Gillette.)

Siendo S = la parte de arena para 1 de cem, tenemos:

$$W = (8S + 24) \div (S + 1).$$

Esto da

| cuando S = | 1 | 1.5 | 2.0 | 2.5 | 3.0 | 3.5 | 4.0 |
|---|---|---|---|---|---|---|---|
| W = | 16 | 14.4 | 13.3 | 12.6 | 12.0 | 11.5 | 11.2 |

Falk encuentra que los morteros en estas proporciones se adhieren bien al acero.

**38.** El cem de escoria exige mucha agua para endurecerse bien. Por tanto, si se usan al aire los morteros de cem de escoria, deben mantenerse húmedos.

### Fragua y endurecimiento.

**39. La fragua**, ó pérdida de plasticidad, tiene lugar pocas horas (á veces pocos minutos) después de mezclar el cemento con el agua; mientras que el definitivo **endurecimiento** y **aumento de resistencia** (que aparecen como resultado de otros procesos químicos) se efectúan á menudo en meses y aun en años.

**40. Los bloques de cemento Portland** hechos en moldes, aun de 50 toneladas de peso, se pueden manipular y llevar á su destino, de 1 á 2 semanas después de hechos.

### Fragua inicial y final.

**41.** La fragua inicial y final son etapas del proceso general de la fragua, distinguidas arbitrariamente por razón de la resistencia que presenta el mortero á la penetración de alambres cilíndricos de diámetros y con pesos normales, haciendo que el extremo embotado descanse en una torta, hecha del mortero, en un molde cilíndrico chato, sobre una lámina de vidrio. (Véase 8, pág. 1281.)

### Determinación de la fragua.

**42. El general Totten** (Gen. Q. A. Gillmore, sobre « Cales, Cementos y Morteros », pág. 80) en Fort Adams, R. I., antes de 1830, empleaba un alambre de 2 mm de diám con peso de 100 grms, y de 1 mm de diám con peso de 450 grms tomando como fragua inicial y final el momento en que estos alambres no producían impresión en el mortero.

**43.** Vicat usaba un solo alambre ó « aguja ». La Asociación de Ingenieros civiles (véanse las Especificaciones pág. 1281) prescribe para esta aguja un diámetro de 1 mm y un peso de 300 gramos. La fragua inicial tiene lugar cuando la punta de la aguja, habiendo penetrado 4 cm dentro del mortero, no puede llegar á 5 mm de la lámina de vidrio; y la fragua final se ha hecho cuando la aguja no deja marca alguna en el mortero. El mortero para la prueba de fragua debe ser de « **consistencia normal** », ó tal que una varilla cilíndrica de 1 cm de diám, con peso de 300 gramos, penetre 1 cm en él.

### Modo de acelerar ó retardar la fragua.

**44.** Algunos de los mejores cem son de fragua lenta. Una capa de cem de fragua muy rápida puede fraguar parcialmente, sobre todo en época de calor, antes que el bloque de mampostería haya sido convenientemente situado y ajustado sobre la capa, y **todo lo que perturbe la fragua después de comenzada es perjudicial**. Por otra parte **los cem de fragua** rápida son, en ciertos casos, los mejores; como cuando están expuestos á aguas corrientes. Se puede retardar la fragua agregando pasta de cal en 5 y 15% de la pasta de cem sin que esto lo debilite seriamente. Los cem nat son en general de fragua rápida. Los de escoria, de fragua lenta.

**45.** En general **la fragua se acelera** por exceso de alúmina y por la presencia de soda y potasa en el cem, por la frescura y fineza de éste, por el uso de agua y arena caliente en la mezcla y por el tiempo cálido. La fragua se retarda por exceso de cal y sílice en el cem, por la presencia de arena, por la humedad de la mezcla, por el frío, por presencia de sal ó acido sulfúrico en el agua de la mezcla; por 1 ó 2% de sulfato de cal, hidratada ó anhídrica (yesos), ó cal apagada, en algunos casos por quema fuerte, y en general por la edad del cem, pero el almacenaje de cem nuevos en lugares calientes los acelera.

**45 a. Yeso.** Cas $O_4$. La duración de la fragua (inicial y final) aumenta rápidamente, agregándole hasta 2% de yeso, y se hace constante, ó aumenta poco empleando hasta el 4%. (E. Candlot, « Cements et Chaux hidrauliques ».)

**45 b.** El tiempo para comenzar y terminar la fragua aumenta agregándole hasta 1.5% de yeso, pero disminuye si se aumenta hasta 7%. (Kniskern and Gass, Sibley Journ of Engng, enero 1905.)

**45 c. Cloruro de cal,** $CaCl_2$. Una solución suave retarda, pero una concentrada ó fuerte acelera la fragua de los Portland, así: de 10 á 40 grams por litro, el tiempo de fragua es de 500 á 850 minutos; mientras que con 200 á 300 grms por litro, se reduce de 2 á 25 minutos. Los cem ricos ó pobres de alúmina se afectan poco con el cloruro de cal. Una solución suave (de 30 á 60 grms por lit) mejora mucho la calidad de un cem que contiene cal libre, facilitando la hidratación de ésta. (Obra citada de Candlot.)

**45 d.** Empleando ½ á 1½ % de cloruro de cal ($CaCl_2$) seco, molido con ***clinker*** de cem y amasado en tortas de consistencia normal (véase Pruebas, 7, pág. 1281),

aumenta el tiempo de la fragua inicial de 2 á 167 minutos y el de la fragua final de 52 á 275 minutos. Con 6% los tiempos de fragua son de 68 á 145 respectivamente, Kniskern and Gass, Sibley Journ. of Engng, enero 1905.

**46.** La fragua va acompañada de elevación de temperatura. En fraguas rápidas ésta puede alcanzar 10° C ó más.

**47.** Los cementos de fragua lenta alcanzan cierto grado de **endurecimiento** más rápidamente que los de fragua rápida.

**48.** En época de calor los cementos en fragua, al secarse, pierden la humedad de que depende el proceso de endurecimiento. Por lo cual **fraguan sin endurecer.** Se debe tomar toda clase de precauciones para impedir esto en época de calor.

**49.** Cementos de la misma clase difieren mucho en la **rapidez de su endurecimiento.** Al fin del primer mes uno de ellos puede alcanzar la mitad de lo que alcanza otro en un año, mientras que un tercero no llega á la sexta parte; sin embargo, al año pueden tener la misma fuerza. Por esta razón las pruebas de una semana ó de un mes no son nunca concluyentes sobre los méritos comparativos de los cementos.

**50. Se requieren muchos años para alcanzar el máximo de dureza:** pero después del primer año el aumento es muy pequeño y lento, especialmente en el caso de los cementos puros. Además, cualquier aumento subsiguiente es de poca importancia, porque, generalmente, para entonces, y á veces antes, se ha concluído la obra y se encuentra expuesta ya al máximo de su carga.

**51.** Cementos calculados de fragua lenta pueden en la fabricación **hacerse rápidos** (ó de « **relámpago** » « **flashing** ») por el almacenaje, sobre todo en lugares calientes, y si el cemento es pobre en cal. Esto se atribuye á la desintegración de las partículas y consiguiente aumento de fineza. El cambio es á veces muy rápido. Este inconveniente puede remediarse sin reducir la fuerza del cemento, almacenándolo en lugares frescos y agregándole de 1 á 2% de cal apagada. Para trabajos pequeños se pueden agregar algunos terrones de cal á cada barril de agua en la mezcla.

**52.** El requisito de que **aumente un tanto por ciento de su fuerza entre los 7 y los 28 días** provoca en el fabricante el deseo de moler su cemento grueso, ó adulterarlo con materiales inertes, para que no realice aquel aumento en los primeros 7 días.

## Otras propiedades.

### Constancia de volumen.

**53. La variación de volumen** en los morteros de cem es la tendencia á la expansión, contracción ó desintegración en el aire ó en el agua, ó bajo el calor ó frío. (Véanse Especificaciones.)

**54.** Los cementos de fábricas conocidas son rara vez deficientes en resistencia; pero sí pueden sufrir variaciones de volumen, de lo cual depende su durabilidad.

**55.** La variación de volumen **se debe** generalmente á un exceso de cal libre, producida por mala proporción, exceso de quema, falta de sazón, ó molienda gruesa : esta última impide la perfecta hidratación. La presencia de **sulfatos de cal** (yesos) es favorable á la conservación de volumen. Un cemento que varía de volumen se puede mejorar con el **almacenaje.**

**56. Variación de volumen durante el endurecimiento.** El hormigón de cemento expuesto al aire, **reduce** su volumen durante los primeros dos ó tres meses, mientras que se **expande en el agua** en el mismo período. Estos cambios son mayores en los hormigones que contienen mayor proporción de cemento.

**57. Contracción** de los morteros **al aire libre.**

| | por ciento. |
|---|---|
| Cem puro *..... | .132 á .140 |
| Mortero 1 : 1 *..... | .080 á .170 |
| Morteros pobres **..... | .030 á .050 |

La expansión **en el agua** es algo menor que la contracción en el aire. El cambio total de dimensiones es la suma algebraica de la debida á la fragua y á los cambios de temperatura.

**58.** Los hormigones se contraen menos cuando están bajo presión. La finura de la arena es causa de contracción.

** Considère. Investigaciones experimentales sobre el cem armado.

## Resistencia.

**59**. La resistencia á la tracción de los morteros de cem se prueba generalmente por medio de probetas.

**60. Factores que afectan las resistencias**. Influye mucho sobre la resistencia de las muestras ensayadas, la variación de temperatura del aire y del agua, y también la fuerza empleada para comprimir el cem dentro de los moldes; así como también por el grado de fragua al ponerlas en el agua y por el grado de sequedad al sacarlas, y aún más por la presión bajo la cual fragüen, lo que aumenta materialmente la resistencia; por esta razón, los cem empleados en obras de mampostería en circunstancias ordinarias pueden dar mejores resultados que en los ensayos de las muestras. Las causas antedichas, el grado de completa mezcla, la proporción de agua empleada, y otras consideraciones, pueden fácilmente afectar los resultados hasta en un **ciento por ciento** ó más. De aquí las divergencias en los informes sobre los distintos ensayos. Las muestras de diferentes cem, ensayados en condiciones aparentemente iguales, pueden dar muy diferentes resultados.

**61. Ecuación personal**. Durante la construcción del acueducto de « Croton », en Nueva York, un grupo de ensayadores, probando 835 probetas, obtuvieron un promedio de resistencia de 4.36 kg por cm cuad; mientras que otro grupo probando 2,434 probetas exactamente iguales, por los mismos métodos y en idénticas circunstancias, obtuvieron un promedio de 5.95 kg por cm cuad, ó sea 36% más.

**62**. Debido á estas inseguridades **deben hacerse las pruebas con un gran número de muestras** para que tengan valor y para poder obtener promedio de las diferencias.

**63**. Las diferencias en los resultados comparativos entre diversos materiales pueden ser producidas por una ó varias diferencias entre los materiales. Así, al comparar los morteros hechos con arenas limpias y sucias, la resistencia puede sufrir más por la diferencia de densidad de la arena que por su mayor ó menor limpieza.

**64. Efecto de la edad**. El diagrama *, fig. 1, demuestra aproximadamente la resistencia de los cementos Portland normales y de los naturales, puros y con 2 y 3 partes de arena, hasta la edad de dos años.

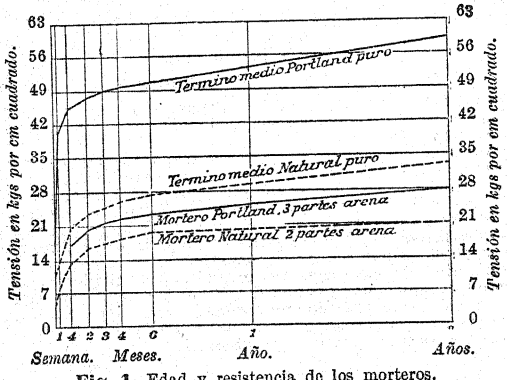

**Fig. 1**. Edad y resistencia de los morteros.

* Véase « Cement » de Richard L. Humphrey. Chicago, mayo de 1899.

**65. La fig. 2 demuestra, aproximadamente, los efectos de la arena,** en diversas proporciones, sobre la resistencia de los cementos Portland y naturales, en diversas edades, desde 1 semana hasta 1 año. Las cuatro curvas continuas representan los promedios de cementos Portland, y las cuatro líneas de puntos los pro-

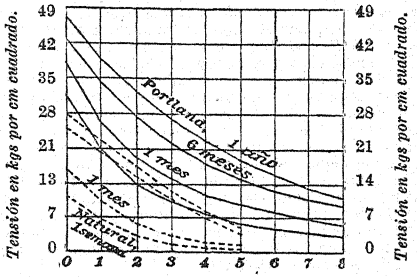

**Fig. 2.** Efecto de la arena sobre la resistencia.

medios de los cementos naturales. Para cada clase de cemento las curvas representan edades de 1 año, 6 meses, 1 mes y 1 semana, respectivamente, comenzando por la parte superior. Las curvas de los cementos naturales se llevan tan sólo hasta 5 partes de arena.

**66. La resistencia á la compresión** de los morteros de cemento, en cubos, parece ser de 8 á 10 veces la de su resistencia á la tensión; la resistencia transversal (esfuerzo cortante) es como ¼ de esta última.

**67.** La adhesión de los morteros de cem á los ladrillos ó á la piedra bruta, en diferentes edades, ya puros ó mezclados con arena, se puede calcular como los ¾ de la resistencia del mortero á la tensión y á la misma edad. Si los ladrillos y las piedras están húmedos y sin suciedades al colocarlos, la adhesión aumenta; mientras que, si están muy secos y sucios, sobre todo en época de calor, puede reducirse casi á cero. La adhesión á los ladrillos muy duros y á las piedras bien talladas, es menor que á las superficies ásperas y porosas.

**68.** El Dr. Bohme, de Berlín, encontró que la resistencia á la tensión, dividida por la de adhesión, era igual á 10 con morteros de 1 : 3 y 1 : 4 y de 6 á 8 con cem puro y mortero de 1 : 2.

## Otros detalles.

**69.** Los morteros de cal y cem, cuando se emplean en construcciones de ladrillos, á menudo desfiguran la obra, especialmente cerca del mar y en climas húmedos, con **eflorescencias** blancas, las que suelen extenderse sobre la superficie de la obra y dañar los ladrillos. También sucede, hasta cierto punto, con los cem Portland y en las juntas de las mamposterías de piedra, aunque en menor escala. Esto daña sólo á las piedras porosas. Generalmente es un carbonato de soda ó de potasa hidratado, ó un sulfato de magnesia unido á veces á otras sales. Como preventivo, el general Gillmore recomienda se agregue á cada 300 kg de cem en polvo, cien de cal viva, y de 8 á 12 de cualquier grasa animal barata, incorporando ésta muy bien á la cal viva antes que se apague y antes de agregarla al cem. Se dice que el aceite de linaza en proporción de 2 galones por cada 135 kg de cem seco, con cal ó sin ella, impide la eflorescencia en los casos dichos; pero, como la grasa, retarda mucho la fragua y debilita el cem. (Véase Ladrillos, pág. 1267.)

**70.** Para **recalzar** las juntas se debe emplear el mejor cem Portland puro, á menudo se usa mezclado con una ó dos partes de arena. Mézclese bajo techo y en cantidades como de dos litros cada vez, usando poca agua, de manera que el mortero, al usarlo, aparezca más bien incoherente y deficiente en plasticidad. Las juntas deben limpiarse y rasparse bien, hasta un centímetro ó más de profundidad, aplicando el mortero con cuchara adecuada; si la junta es recta, se mantiene debajo un instrumento de filo recto como auxiliar. Luego se calafatea bien el mortero hasta llenar la junta y se la pule con fuerza. Si son muy angostas, se ensanchan á

cincel lo suficiente. La junta se humedece bien antes de rellenarla y luego se la protege del sol para que no se seque demasiado pronto.

### Hormigón de cem bajo el agua.

**71. Lechosidad.** « Cuando los hormigones de cemento están bajo el agua, sobre todo en el mar, el cem exuda un fluido gelatinoso que flota en la superficie, dándole al agua un tinte lechoso, llamado por los franceses *laitance*. Como en estas condiciones á veces fragua de modo imperfecto, y algunos cem casi no fraguan, su interposición en las contrucción, aun en cantidades pequeñas, tiende á disminuir la continuidad y fuerza de la masa. Se acostumbra extraerlo de los espacios que ocupa por medio de bombas, trabajo que debe hacerse con cuidado para evitar daños en la construcción causados por las corrientes que se forman por la acción de las corrientes. La lechosidad se disminuye mucho reduciendo el área del hormigón expuesta al agua; también empleando cajas de 1 á 1½ metros cúbs de capacidad para sumergir el hormigón. » (Gillmore, « Cales, cementos hidráulicos y morteros ».)

**72.** Los autores no están de acuerdo sobre los **efectos del agua de mar.** H. Le Chatelier (International Assn for Testing Materials, Procs. 1906) encuentra que á los ingredientes activos del cem (cal, alúmina y sílice) los afectan las sales de magnesia del agua de mar, produciendo cloruro de calcio y sulfato de cal solubles. Este último, con el aluminato de cal, forma un compuesto cuya cristalización tiende á hinchar y agrietar el material.

**73.** Parece que las aguas, y en especial la de mar, con sus numerosas sales, y por su poder de infiltración en el cem, deberían pronto cerrarse ellas mismas la entrada al interior de la masa.

**74. La sustitución de hierro por alúmina**, en los cem, elimina uno de los más activos agentes de deterioro del agua de mar. (Véase Cem, § 30, pág. 1018.)

**75. Sobre la desintegración de estos hormigones en agua** (salada ó dulce) influye menos el agua misma que la alternada acción de las heladas, cuando el hormigón se encuentra expuesto á aquéllas por las variaciones del nivel de las aguas.

**76.** En algunos puertos de Italia existen morteros de puzolana y cal que se han conservado en perfecto estado y tienen ya de 15 á 20 siglos.

**77.** En el astillero de Kobe, en el Japón, se reemplazó dentro del dique el agua salada por agua dulce, para impedir los deterioros causados por aquélla, haciendo entrar la dulce por la superficie, mientras que la salada, más densa, se extrae por el fondo con bombas.

# CONCRETO *

**Para cemento, arena y mortero,** véanse págs. 1268, etc.

## AGREGADOS **

### Constituyentes.

**1. Orden de su valor.** (1) Trap (roca volcánica de la especie del basalto), (2) granito, (3) cascajo, (4) mármol, (5) piedra caliza, (6) escorias, (7) asperón, (8) pizarra, (9) esquisto, (10) ceniza gruesa.

**2. La resistencia del concreto,** con buen asperón, es como de .75 × resist con roca volcánica. Con pizarra, menos de la mitad de la misma. Buenas cenizas gruesas igualan á la pizarra y al esquisto. La dureza de los agregados aumenta en importancia con la edad del concreto, « porque, á medida que el cemento se endurece, hay mayor tendencia de las piedras mismas al esfuerzo cortante y así entra en juego la dureza de los agregados ». (Sanford E. Thompson, E. R., '06 /enero 27, pág. 109.)

**3.** La elección de los agregados es naturalmente cuestión de **costo** y de resistencia, etc., del producto. Así, con cascajo suficientemente barato, comparado con la piedra triturada, puede ser económico usar el cascajo, ó una mezcla de cascajo y piedra, y para obtener la resistencia total requerida se usa mayor masa de concreto. Esto es conveniente en cimientos, sobre terreno débil, porque distribuye la carga sobre un área mayor.

**4.** En muchos casos, la elección de la arena y agregados depende en gran parte del material que puede obtenerse y de su distancia.

**5.** Donde el cemento es barato, puede ser económico usar materiales más cercanos y conseguir la calidad aumentando el cemento.

**6.** La piedra que se rompe en fragmentos próximamente cúbicos, se aprieta mejor que la que se astilla en pedazos largos, y los fragmentos son menos susceptibles de romperse terminada la obra.

**7.** Buena piedra rota es mejor que cascajo. La aspereza de las partículas de piedra parece que da mejor adhesión.

**8.** A veces se usan cenizas gruesas para el agregado. Ellas son de ordinario las que resultan de la quemada de carbón bituminoso bajo las calderas. El material es en su mayor parte una ceniza fina, que contiene considerable cantidad de carbón no quemado.

**9.** Las cenizas gruesas de **antracita** se usan menos por ser menos abundantes.

**10.** El **conc** de ceniza gruesa, que sólo pesa de 1,280 á 1,600 kg por metro cúb, es ventajoso cuando se requiere poco peso. El conc de piedra rota ó cascajo pesa de 2,240 á 2,320 kg por m cúb.

**11.** La arcilla ó el barro que se adhiere á las partículas de cascajo destruye ó debilita la adhesión de los morteros á las piedras. La Comisión de Tránsito de Boston, Informe para 1901, pág. 39, encontró que la relación de las resistencias, entre conc con cascajo limpio y con cascajo sucio, es como de 60 á 45. Véase « Arcilla y Barro », en « Arena » é « Ingredientes accidentales », pág. 1346 y 1347.

### Tamaño.

**12.** En vigas, arcos, etc., el **tamaño del agregado** no debe exceder de 4 á 5 cm en ninguna de sus dimensiones; pero, si se limpia bien de polvo tamizándolo ó lavándolo, y si el mortero llena completamente los huecos, todos los tamaños, desde 1 á 10 cm, podrán usarse en obras de volumen, como cimientos, presas, muelles, etc.

**13.** Con agregados gruesos debe usarse arena gruesa y viceversa.

**14.** De ordinario se economiza cemento tamizando la arena del cascajo ó el material fino de la piedra triturada y luego remezclándolo en las proporciones requeridas.

---

* *N. del T.* — Adoptamos esta expresión, cuyo uso se ha generalizado tanto, para reemplazar la de hormigón de cemento que es muy larga. La palabra concreto la abreviaremos así : *conc.*

** Por « agregado » significamos los materiales sólidos del concreto que no son el cemento y la arena. El término « agregado » se extiende también á veces á la arena.

### Densidad.

**15.** Cuando un cuerpo sólido se reduce á una masa que consiste en pedazos rotos separados por huecos, el aumento de volumen se debe solamente á los **huecos**, y es igual al espacio ocupado por ellos. En consecuencia, la razón entre el **aumento de volumen** y el volumen primitivo, es la de los huecos al volumen **primitivo**, y no al volumen final. Así, si un metro cúbico de piedra sólida, después de rota en pedazos, ocupa dos veces el espacio de antes, entonces el aumento de volumen, ó el espacio ocupado por los huecos, es=al ocupado por los pedazos sólidos=la mitad del ocupado por toda la masa rota.

**16.** En la piedra rota aflada y angular, que tenga todos sus pedazos de tamaño casi uniforme; cuando se mida suelta, como el 50 por **ciento** del volumen serán **huecos**. Si los tamaños de las piedras varían entre límites algo amplios, como desde 5 cm hasta ½ cm, el volumen ocupado por los huecos será menor, á menudo sólo de 28 á 30% del total.

**17. Las pruebas** hechas por el Sr. Wm. Hall (Trans. A S C E, vol 42, 1899, pág. 132) con piedra caliza azul de Río Verde triturada hasta 6 cm, tamizada y mezclada con cascajo muy limpio del río Ohio, de 4 cm, dieron el siguiente resultado:

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| Tanto por ciento de piedra..... | | | 100 | 80 | 70 | 60 | 50 | 0 |
| — | — | cascajo..... | 0 | 20 | 30 | 40 | 50 | 100 |
| — | — | huecos..... | 48 | 44 | 41 | 38½ | 36 | 35 |

Estos son términos medios de un número de pruebas de varias gabarras de materiales, pero se hicieron pocas variaciones entre las mezclas.

### Concreto ciclópeo.

**18-19.** El « concreto ciclópeo », que consiste en piedra bruta, grande, colocada en mortero de cemento, se usa en general, económica y ventajosamente, en obras de volumen, especialmente en represas donde se requiere mucho peso y esfuerzo cortante horizontal. No es necesario que las piedras sean chatas. Déjanse caer ordinariamente en el mortero mojado, asentándolas sólo por su caída. El concreto mojado facilita el asentamiento de las piedras, y se liga mejor con ellas que el seco.

**20. En la presa de la caída de agua de Chaudiere**, Canadá, los bloques se obtuvieron de capas duras en el lecho del río, con buena forma para asentarlas. El volumen del agregado varió entre 25 y 30% del volumen de la presa; máx, 40%.

**21.** En las obras de Desenvolvimiento en Transmere Bay (Procs. Inst. C. E., vol. 171, 1908, pág. 145) los bloques eran de asperón. Cerca de las bases de los muros, pesaban una tonelada ó más. La proporción de los bloques disminuyó, con el espesor del muro, desde 10 hasta 7% de la masa total.

**22. Las restricciones innecesarias** que suelen imponerse á los contratistas pueden suprimir la ventaja debida al uso de los bloques. (Véase § 19.)

## CONCRETO COMÚN

**1. El concreto de cemento** se compone con piedra rota, cascajo, ceniza gruesa, escoria, conchas, ú otro material duro é inerte* (que es el agregado) adheridos entre sí por mortero de cemento, compuesto de cemento y arena.

### Ventajas.

**2. Las ventajas principales** del concreto son: la comodidad con que puede colocarse, particularmente en situaciones de otro modo difíciles ó debajo del agua; su utilidad en trabajos bajo el agua; su baratura, debida en gran parte á la facilidad para colocarlo, y el hecho de poder usar piedra muy pequeña; sus cualidades de resistencia contra el fuego comparado con la piedra caliza (que se calcina) y con el granito (que se astilla).

**3.** El uso del concreto se ha extendido muchísimo, con el **cemento armado**, que permite su empleo (antes de ahora á menudo impracticable) en piezas sujetas á tensión lo mismo que á compresión, como en los *cantilevers*, presas, muros de sostenimiento, en columnas, y en arcos en que la altura es ó muy grande ó muy pequeña

* Sin afinidad química por otros materiales.

relativamente á la luz. El cemento armado permite el uso de secciones mucho menores que las empleadas antes con seguridad cuando sólo se hacía uso de la resistencia *compresiva* del material.

**Para cemento armado**, véase pág. 1320.

**4. Desventajas.** El concreto es algo más débil que la buena mampostería de piedra, y tiene sólo como la mitad de la resistencia de la mampostería de granito de primera clase con juntas delgadas de cemento. A semejanza de la piedra y del mortero, está sujeto á deterioro, especialmente en el agua de mar; pero esta dificultad se está eliminando por el esmero con que se hace la manufactura de cemento, alentados por su extenso uso y por su elaboración en grande escala. Como en toda obra humana, y notablemente en las construcciones de albañilería, es necesario mucho cuidado, pues de éste depende en gran parte el éxito de la construcción. La calidad de la obra acabada puede, sin embargo, probarse por taladros.

**5.** El concreto se usa para poner á nivel cimientos de niveles desiguales, antes de colocar las capas de mampostería. Por este medio se empareja el número de capas horizontales en la mampostería y se impide que se asienten desigualmente.

**6.** En trabajos de ferrocarril, el empleo del concreto puede **evitar el uso de grúas** (*derricks*), que son fuente de estorbo y de peligro para los trenes.

**7.** El concreto se usa ventajosamente para **reforzar y proteger la mampostería vieja de piedra**; pero, á menos que se tomen precauciones especiales, las dos construcciones son susceptibles (al cabo de cierto tiempo) de separarse, debido á que se asientan desigualmente, sobre todo si el apisonado no ha sido perfecto.

## Cemento natural.

**8. El cemento natural** rara vez se usa ahora en concreto, excepto en obras de volumen donde no está sujeto á la acción deteriorante del agua ó de la helada y en que no se requiere pronta resistencia. Es apropiado para bases y para muros bajos de sostenimiento no sujetos á vibraciones fuertes.

**9.** En presas, rompeolas, etc., la parte interior es frecuentemente de *cemento natural*, con una envoltura exterior fuerte de concreto de cemento Portland.

## Proporciones.

**10. Las proporciones de cemento, arena y agregado** deben **determinarse** teóricamente, ya todos por peso, ya todos por volumen y estando el polvo suelto; pero, en la práctica, el cemento se mide por el número de sacos ó barriles, etc., usados cuyo contenido se conoce; la arena y el agregado se miden sueltos.

## « Mezcla natural ».

**11. Acostúmbrase designar** las cantidades de cemento, arena y agregado, en un concreto, por proporciones. Así : 1 : 2 : 4 quiere decir 1 parte de cemento con 2 partes de arena y 4 partes de agregado. Tal designación es necesaria al dar instrucciones á los trabajadores; y, cuando las series de tamaños de las partículas son conocidas, ella indica la condición del concreto. Las proporciones se rigen naturalmente por la naturaleza de la obra; pero no deben hacerse distinciones entre trabajos de clases próximamente semejantes.

**12. Proporciones usadas para concreto de cemento Portland :**

En obras excepcionalmente sólidas (nivelación de cimientos, represas, rompeolas), 1 : 1.5 : 8 á 1 : 5 : 10; con cemento natural, 1 : 2 : 5.
Cimientos, generalmente, 1 : 3 : 6; á veces sólo 1 : 4 : 8.
Muelles, pedestales, estribos, 1 : 2½ : 5½ á 1 : 3½ : 7.
Estribos y bóvedas en los filtros, 1 : 2½ : 5½.
Muros y vigas armados, 1 : 3 : 6; secciones ligeras, 1 : 2½ : 5.
Cimientos, 1 : 2½ : 5½; muros de sostenimiento, 1 : 2½ : 5½ á 1 : 3 : 6.
Muros de enjutas ó riñones, 1 : 3 : 6.
Conductos, desagües, cloacas, 1 : 2½ : 5½ á 1 : 3 : 6.
Muros para estanques de agua y filtros, 1 : 1½ : 3½ á 1 : 2½ : 5½.
Obras bajo el agua, 1 : 2 : 3.
Sistemas de pisos (vigas, losas), 1 : 2 : 4 á 1 : 2½ : 5½.
Escaleras y techos, 1 : 2 : 4.
Arcos, 1 : 2½ : 5; secciones ligeras, 1 : 2 : 4.
Albardillas y asientos de puente, 1 : 1 : 2 á 1 : 2 : 4.

Pero el requisito esencial es que todos los huecos, entre las partículas de arena y el agregado, se llenen de mortero de cemento. En consecuencia, á menos que la gradación de los tamaños, de arena y de agregado, sea conocida, ó supuesta, el simple enunciado de las proporciones, de cemento, arena y agregado, en una mezcla, es sólo un dato poco útil en cuanto al valor del concreto.

**13.** En general, **en obras de cemento armado** deben emplearse mezclas más ricas que las que se usan en obras de grandes masas. A fin de conseguir una adhesión conveniente y firme, que es lo más importante, las barras deben estar completamente rodeadas por el cemento.

### Materiales requeridos.

**14. Materiales requeridos para un metro cúbico de concreto de cemento Portland apisonado.** $c$=cemento, bls; $s$=arena, metros cúbs; $a$=agregado, metros cúbs. Se suprime el polvo al cernirlo. Las piedras no más grandes de 2½ cm.

| Mezcla | $c$ | $s$ | $a$ |
|---|---|---|---|
| 1 : 2 : 4 | 1.89 | .57 | 1.16 |
| 1 : 2 : 5½ | 1.55 | .60 | 1.18 |
| 1 : 3 : 5 | 1.44 | .66 | 1.10 |
| 1 : 3 : 6 | 1.31 | .60 | 1.19 |
| 1 : 3 : 7 | 1.18 | .55 | 1.20 |
| 1 : 4 : 7 | 1.02 | .66 | 1.16 |
| 1 : 4 : 8 | 1.00 | .61 | 1.21 |

Con piedra de 6 cm, las cantidades de todos los materiales, por m cúb de concreto, fueron aumentadas de 2 á 5%. Con cascajo, >2 cm, fueron disminuídas como en 9%. (Chas. A. Matcham. Natl. Builders' Supply Assn., 1905.)

**15.** Sean

B=N.° de barriles de cemento requerido por m cúb de concreto
=N.° de veces .108 m cúb de cemento requerido por m cúb de concreto
P=partes de arena (ó agregado) para 1 parte de cemento.

Entonces

1/B=N.° de m cúb de concreto hechos con 1 barril de cemento;
.108 P=N.° de m cúb de arena (ó agregado) para 1 barril de cemento;
.108 PB=N.° de m cúb de arena (ó agregado) para 1 m cúb de concreto.

### Vacíos. Véase Peso, pág. 1314.

**16. Reducción de los vacíos.** Si se usan piedras que tengan 50% de huecos, y arena que tenga 50% de huecos, con cemento, en las proporciones:

Cemento, 1 parte = .25 m cúb;
Arena, 2 partes= .50 m cúb;
Piedra, 4 partes=1.00 m cúb;

el concreto resultante medirá algo más de un m cúb, y sin embargo contendrá huecos no llenados.

**17.** Estas proporciones, sin embargo, no son económicas. Eligiendo una arena que tenga una serie de tamaños, ó mezclando dos ó más arenas que tengan granos de diferentes tamaños, los huecos de la arena pueden reducirse á, digamos, 33%. De manera semejante, los huecos en la piedra pueden reducirse á 35%. Digamos pues, que tenemos:

Cemento, 1 parte = .12 m cúb;
Arena, 3 partes= .36 m cúb;
Piedra, 8 partes=1.00 m cúb;

con resultados tan buenos como con la mezcla precedente de 1 : 2 : 4, aunque usando sólo la mitad del cemento.

**18.** El Sr. Geo W. Rafter (Trans. A. S. C. E, dic. de 1899, vol. 42, pág. 106) recomienda que las proporciones se expresen por medio de la razón del volumen del mortero al volumen del agregado. Así: un concreto que contenga 75 volúmenes de agregado y 25 volúmenes de mortero, sería un concreto de 33⅓ %.

**19.** En condiciones usuales, los **huecos** en el **agregado deben llenarse** de

un mortero tan rico como lo exija la fuerza de la obra. Puede resultar un concreto mejor del uso de un mortero pobre que llene los huecos que del uso de un mortero más rico que no llene los huecos sino parcialmente.

**20.** El mortero no puede distribuirse uniformemente en todo el agregado, y algunos de los vacíos son demasiado pequeños para admitir los granos de arena. Además, la mezcla es susceptible de alteraciones al depositarse. En consecuencia, habrá huecos en el concreto, á no ser que haya un exceso de mortero sobre los vacíos calculados en el agregado.

**21.** En la práctica, el **exceso de volumen de mortero requerido**, sobre el de los vacíos medidos en el agregado, á fin de conseguir que queden llenos, es generalmente de 15 á 25% del volumen de los vacíos. Pero, por 15 experimentos con piedra caliza, encontró el prof. Baker que los huecos no se llenaban completamente, á no ser que el volumen del mortero excediese del volumen de los vacíos en 40%. (Tabla 13 *c*, pág. 112 *b*, *Baker's Masonry Construction*, 1907.)

**22.** El Sr. John Watt Sanderman (Procs., Instr. C. E., vol. 121, pág. 219, 1895) cree que, para **garantizar la impermeabilidad**, el volumen del mortero debe ser 50% del volumen del agregado que tenga 35% de vacíos; ó bien el exceso de mortero=43% de los vacíos.

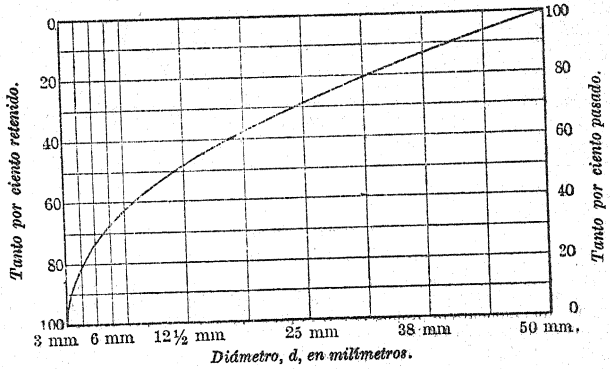

**Fig. 1.** Parábola de densidad máxima. Véase § 23.

**Densidad.** Véase Peso, pág. 1314.

**23.** El Sr. Wm. B. Fuller (T. and T. pág. 197) encuentra que se obtiene la **mayor densidad**, y en consecuencia la menor cantidad de cemento requerida, cuando el agregado y la arena están graduados de modo que los tantos por ciento, por peso, que pasan por los varios tamices, están como los indican las ordenadas de la parábola en la fig. 1, donde las abscisas son los diámetros, *d*, de las aberturas en los tamices; mientras las ordenadas *debajo* de la parábola representan los tantos por ciento *pasados* y las de *encima* los tantos por ciento *retenidos*, por estas aberturas respectivamente.

**24.** En esta parábola $d=P\sqrt{M}$; donde $d$=un diámetro dado; P=proporción de partículas más pequeñas que $d$; M=diámetro máx de piedra (=2 pulgs (50 mm) en la figura).

**25.** Los experimentos (Trans. A. S. C. E., vol. 59, págs. 67, etc., 1907) muestran que puede efectuarse un ahorro de 12% de cemento y obtenerse un producto más impermeable graduando así los tamaños de la arena y del agregado; pero el ahorro puede á veces ser destruído por el costo adicional de tal graduación, especialmente en obras pequeñas.

(*Obs. del T.* — Como siempre, en el ejemplo que sigue convertimos los datos del autor al sistema métrico.)

**26.** En el revestimiento del túnel para el acueducto de Sudbury :

| | |
|---|---|
| 1 barril de cemento Portland como venía del vendedor.... | = 97.0 litros |
| $2^1/_0$ barriles de arena suelta..... | =208.4 — |
| $5\frac{1}{2}$ barriles de piedra triturada suelta..... | =526.0 — |
| Total..... | =831.4 — |

Sacudiendo ligeramente la arena y la piedra, se hicieron prácticamente las proporciones 1 : 2 : 5.

Estos 831.4 litros produjeron de 566 á 595 litros de concreto, apisonado en el lugar; ó digamos, 1,400 litros de materiales para 1,000 lit, ó un m cúb de concreto.

**27.** El Sr. Wm. B. Fuller (Asociación Nacional de los que emplean cemento Procs., '07, pág. 95) probó vigas de concreto, de 30 días, de 1 : 2 : 6, 1 : 3 : 5, 1 : 4 : 4, 1 : 5 : 8, 1 : 6 : 2, 1 : 8 : 0 (todas 1 : 8). Las fuerzas comparadas como en la fig. 2 *.

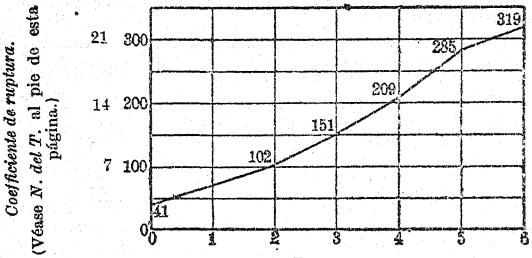

**Fig. 2.** Proporciones; resistencia.

**28.** De esto aparece que, cuando los huecos en el agregado están llenos de mortero, la fuerza de compresión del concreto parece más bien aumentar que disminuir á medida que aumenta la proporción de la piedra, y además, que depende en gran parte de la riqueza del mortero.

**29. Graduar las proporciones por mezclas de ensayo.** (Wm. B. Fuller, Trans. A. S. C. E., vol. 59, págs. 77, etc.)

Habiéndose determinado las clases de arena y piedra que han de emplearse en cualquier obra, úsese un cilindro corto, fuerte y rígido, de hierro forjado de 25 cm (forma de un tubo de agua), cerrado con un casquete en un extremo.

**30.** Sobre un pedazo de lámina de acero ú otro material no absorbente, pésense y mézclense todos los ingredientes, hasta la consistencia requerida para la obra. Échese la mezcla dentro del cilindro, apretándola cuidadosa y continuamente, y anótese la altura hasta donde se llena el cilindro. Antes de que la mezcla tenga tiempo de fraguar, vacíese y límpiese el cilindro.

**31.** Hágase otra cantidad de mezcla, usando los mismos pesos de cemento y de agua que antes, y el mismo **peso total** de arena y piedra, pero con una proporción ligeramente *diferente de los pesos* de la arena y de la piedra.

**32.** Nótese la altura alcanzada, en el cilindro, por esta segunda y por las subsiguientes mezclas. La mejor mezcla es la *que da la menor altura en el cilindro*, con tal que su aspecto en el cilindro demuestre que todas las piedras están cubiertas de mortero.

**33.** Este método pone al ingeniero en situación de escoger los mejores de los materiales disponibles en cualquier caso dado.

---

* *N. del T.* — Frente á los números 100, 200, 300 del dibujo, que indican lbs por pulg cuad, están respectivamente 7, 14, 21, que son los kg por cm cuad, á que equivalen. Para valores intermedios sirve la misma escala de la figura. Los números 41, 102, 151, etc., del interior del clisé multiplicados por 0.07 dan los valores en kg por cm cuadrado de los puntos, respectivos en la curva.

**Consistencia.** Véase también Mortero, §§ 34, etc.

**34.** La habilidad y el cuidado, en la colocación, y la *uniformidad* en la consistencia son más importantes que la misma consistencia.

**35.** Los extremos de la **práctica** son : (1) Concreto con mortero apróximadamente tan húmedo como tierra húmeda; usar tan sólo el agua suficiente para que aparezca en la superficie después de atacarlo mucho y fuerte, (2) usar suficiente agua para hacer que el concreto tiemble cuando se pone por primera vez, y que sólo permita su colocación con las palas. La consistencia conveniente depende en gran parte de la naturaleza y objeto de la obra.

**36.** El concreto **seco** es preferible generalmente en obra grande abierta donde puede ser bien apisonado, y donde se necesita que adquiera pronto su resistencia, como en los arranques de los arcos. Cuando está bien apisonado desarrolla una resistencia á la compresión muy superior, y en poco tiempo, y puede llegar á tener una resistencia permanente algo mayor que las mezclas más húmedas; pero el apisonado imperfecto de estas mezclas puede dar por resultado un concreto muy débil, mientras que el apisonado perfecto puede hacer la obra más costosa de lo que justificaría el aumento de resistencia adquirido.

**37. Mediano.** La práctica actual favorece el uso, en general, de mezclas suficientemente húmedas para requerir sólo el paleo; pero, aun en este trabajo, puede necesitarse el apisonado de tiempo en tiempo para mezclas ocasionalmente secas.

**38.** El concreto **húmedo** se mezcla mejor, se coloca más pronta y económicamente y se hace entrar con más facilidad en los espacios estrechos entre las barras en el cemento armado. Se pone en más perfecto contacto con los moldes y armaduras, tomando así una superficie más lisa y más impermeable. Es, por consiguiente, preferible así (en edificios) en armaduras de forma complicada, ó en secciones delgadas, ó donde se requieren superficies lisas.

**39.** La **humedad** retarda la fragua, une mejor las capas sucesivas, da una masa compacta con menos pisón y suministra el aumento de agua requerida para suplir la absorción por las armaduras de madera. El concreto húmedo está menos expuesto que el seco á sufrir por mala mano de obra; pero un exceso de agua reduce la fuerza y aumenta la eflorescencia.

**40.** En el concreto « ciclópeo » pueden emplearse más piedras grandes cuando el concreto es húmedo; éste les permite asentarse bién y se une mejor con ellas.

**41.** Se usan con frecuencia las mezclas **suficientemente húmedas para echarlas** en las armaduras de las columnas de los pisos.

**42.** La humedad de la atmósfera reduce considerablemente la cantidad de agua requerida para una consistencia dada.

**43.** El agua sube al través de concreto colocado. En consecuencia, una proporción menor de agua en la mezcla puede bastar hacia el fin de un día de trabajo.

## MANIPULACIÓN Y MEZCLA

### Ingredientes.

**1.** Al proyectar una oficina (planta) para **elaborar** concreto deben tomarse en cuenta las cantidades que han de manipularse, las áreas sobre que deben distribuirse, las facilidades para conseguir y recibir los materiales, y el espacio de trabajo disponible; además, cada caso presentará peculiares circunstancias.

**2.** Las *disposiciones* de tales oficinas son tan variadas por su naturaleza como lo son las diversas clases de trabajo. En general, en cada obra debe estudiarse este punto muy especialmente, y el buen éxito y la economía dependen en gran parte de lo adecuado de esta oficina de manipulación.

**3.** Los materiales pueden llegar al sitio por carros, botes ó yuntas. Téngase cuidado de que no haya lodo ni esté sucio el fondo del vehículo. La arena y el agregado pueden dragarse del río.

**4.** Después de llegar á la obra, son llevados los materiales á los depósitos, por carretas, carretillas, carros pequeños, baldes, ó por cables. De los depósitos se llevan de ordinario por su propio peso, por medio de tolvas, al mezclador.

**5. Almacenaje.** El cemento se guarda comúnmente en tinglados ó almacenes y se manipula, separadamente de la arena y el agregado, en sacos ó barriles, á menudo por medio de conductores de cadena.

**6.** Para llevar los materiales de los **depósitos á los mezcladores**, y el concreto de los mezcladores á la obra, úsanse vagones, carretillas ó carros pequeños.

**7.** Cuando la obra cubre un área horizontal limitada, como en el caso de un edi-

ficio, pila ó estribo, **el mezclador** no necesita ser movido frecuentemente y su manejo es relativamente sencillo.

**8.** Cuando la obra cubre una gran área horizontal, como en un filtro de lenta filtración, ó donde cruza un valle, como en una presa, úsanse cables, con torres; ó se instalan una ó más plantas de mezclar, en sitios adecuados.

**9.** Cuando la obra se extiende á lo largo de una línea de considerable longitud, como en muros, cloacas ó acueductos, se tiende á lo largo de ella una vía de ferrocarril, á menudo vía ancha, con tres ó más líneas de carriles, y los materiales se manejan desde los carros de grúas; en general de modelos especialmente dispuestos para la obra que se tiene entre manos.

**10.** La obra se facilita teniendo los carros, carretillas, baldes, etc., de capacidad conocida, de modo que puedan servir de medidas al proporcionar la arena y el agregado. Así, los carros pueden contener arena ó agregado bastante para una mezcla y pueden voltearse en cajas más grandes, que contengan cada una arena y agregado en la proporción debida. El cemento se mide por lo común separadamente, contando los sacos ó barriles vaciados.

**11.** Cuando se usan **vagones**, pueden moverse por locomotora ó por cable, llegando á los depósitos por un plano inclinado.

**12.** En el caso de un **transmisor de correa ancha**, la arena y la piedra en debida proporción, y después el cemento, los toma ó se ponen en el cable desde los respectivos depósitos.

**13.** Comúnmente la **plataforma de medir** (ó la tolva de medir para máquinas de mezclar) se coloca directamente sobre el mezclador.

**14.** Para el mayor rendimiento, debe haber dos juegos de tolvas de medir, uno que esté volteándose en el mezclador mientras el otro está llenándose.

Para el lavado de la arena, véase ARENA, § 34.

**15. El agregado puede lavarse** en una criba cilíndrica giratoria, con un chorro de agua, bajo alta presión.

**16.** El trabajo se hace con frecuencia **de noche.**

**17. Planta portátil de mezclar concreto** (carro de plataforma). Se compone de dos maderos de 15 × 20 cm y 17 m de largo, á 1.20 m de distancia, colocados sobre el piso de un carro de plataforma de 11 m en ancho de vía corriente, proyectándose sus extremos 3 m fuera de cada extremo del carro, sostenidos por vientos á una armazón elevada en el centro del carro. Cada extremo lleva una tolva como de 1½ m cúb. La arena y el agregado se vierten con palas en esta tolva y se descargan en un conductor de cable que corre horizontalmente debajo de la tolva y que lo conducen hacia arriba á una de las tolvas (de 2 m cúb) situada 4.5 m por sobre el piso del carro y encima del centro de éste. Esta tolva elevada descarga la arena y el cascajo en un mezclador Smith de .57 m cúb, colocado en el centro del carro. El cemento se lleva al mezclador á brazo; el agua se toma de un tubo tendido á lo largo de la obra y provisto de conexiones de manguera. Un barril lleno de agua, y colocado sobre la armazón, sirve de depósito para casos imprevistos. La correa conductora, de 60 cm de ancho, consiste en dos cadenas de eslabones, unidas por una correa de lona fuerte de doble espesor. La correa está sostenida por travesaños de tubo de hierro forjado, á distancia de 45 cm. La correa forma senos entre las crucetas. Es movida por una máquina de vapor que hace girar un cilindro simple de 23 × 40 cm, montado en un extremo del carro. Capacidad media, 209 m cúb por día. Una tolva más baja es suficiente para abastecer al mezclador.

**18.** En la construcción de obras de forma circular, el concreto para pisos, columnas, vigas y techos, puede llevarse á las armaduras por medio de una torre central y un puente que atraviese la obra y llegue á una vía circular. El puente forma entonces una **grúa giratoria** que lleva mezcladores en su extremo.

## Mezcla.

**19. Generalidades.** Cada grano de arena debe ir cubierto de cemento; el mortero debe cubrir cada fragmento de piedra del agregado y debe estar igualmente distribuído en toda la masa. La piedra, si está seca, debe mojarse antes de agregarla al mortero.

**20. La perfección** de la mezcla es de la más grande importancia; especialmente cuando el concreto es pobre de cemento ó de consistencia seca.

**21.** La gran resistencia del concreto en el puente de Munderhingen se atribuye á su perfecta mezcla. Los materiales se mezclaron secos 2 minutos y 3 minutos mojados.

**22.** La variación de **color** de la mezcla indica cambio en las proporciones de los ingredientes.

**23.** Cuídese de que cualquier cemento, rechazado como defectuoso, sea reemplazado por otro bueno.

**24. Elevación del concreto.** Cuando la plataforma de mezclar no puede construirse cerca de la parte superior de la estructura, puede subirse el concreto por medio de un elevador á vapor hasta un nivel conveniente, y entonces se lleva por carriles á nivel. Para elevaciones pequeñas y cantidades pequeñas, se usan elevadores con fuerza de sangre; para elevaciones más altas y cantidades más grandes, se emplea una pequeña máquina de vapor ó de gasolina.

**25.** En algunos casos, el mezclador y su armazón son elevados completamente por la grúa que suministra materiales, y los deposita sobre la obra ó cerca de ella.

**26. La mezcla á brazo** es inaconsejable y antieconómica, excepto en trabajos pequeños.

**27.** En la mezcla hecha á brazo se acostumbra mezclar la arena y el cemento secos, volviéndolos con palas dos ó tres veces, hasta que la mezcla sea de color uniforme y cada grano de arena esté cubierto de cemento.

**28.** Agrégase entonces agua y se mezcla el mortero antes de añadir el agregado; ó el agregado puede esparcirse sobre la arena y el cemento mezclados en seco ó vertidos éstos sobre el agregado, mojando entonces el todo, mezclándolo con palas hasta que el agua se haya incorporado por completo.

**29.** La mezcla del cemento y la arena primero, como se dice arriba, reducen el trabajo total omitiendo la innecesaria manipulación del agregado.

**30.** La mezcla á brazo debe estar bien protegida del viento y la lluvia. El viento se lleva lo más fino (y por tanto lo mejor) del cemento, y la lluvia impide la conveniente mezcla (seca) del cemento y de la arena.

**31.** Para la sub-estación de la *Brooklyn Rapid Transit Co.* se emplearon dos armazones rectangulares sin fondo, una de las cuales tenía una capacidad de 400 lit y se llenó primero de arena. Vaciáronse entonces siete sacos de cemento encima de ella, y la masa se revolvió varias veces por cinco paleros hasta que el color se hizo uniforme. Nivelóse entonces, y la otra armazón (de 800 lit de capacidad) fué puesta encima llenándola de piedra triturada; se le echó agua con una manguera. Revolvióse entonces la masa cuatro veces, se paleó en carretillas y se depositó en las armaduras.

**32.** Con igual cuidado, la mezcla á máquina resulta mejor y más segura que la mezcla á brazo y es más económica en obras grandes.

**33. Debe inspeccionarse cuidadosamente el producto,** pues la obstrucción accidental y no sospechada de una tolva puede cambiar su naturaleza.

## Mezcladores.

**34.** Los mezcladores son **de dos tipos principales** : « continuos » y « por lotes ».

**35.** En los **mezcladores continuos** las materias primas son llevadas continuamente á la máquina por un extremo y el concreto mezclado sale continuamente por el otro extremo.

**36.** El mezclador (continuo) accionado sólo por la **gravedad** es una canal ó artesa estacionaria, colocada casi vertical y provista de aletas ó *estorbos* salientes contra los cuales choca el material en su caída y de los que depende la mezcla. Se da entrada al agua por un tubo de regadera en el tope de la canal. Sólo se necesita fuerza de vapor para elevar los materiales á la parte superior del mezclador, que está generalmente á 2.40 m de altura.

**37. Hay otros mezcladores continuos** en forma de artesas abiertas, casi horizontales y que tienen un eje giratorio longitudinal con aletas adheridas en forma de tornillo, que llevan el material, vertido en el extremo superior, á lo largo de la artesa, al extremo inferior ó de descarga. El agua se suministra por medio de tubos perforados á la largo de los lados de la artesa.

**38. Medida.** En los mezcladores continuos hay que graduar las proporciones de los ingredientes del concreto. Varios medidores automáticos han sido usados. A veces la arena, el cemento y el agregado se esparcen en capas, en la plataforma del mezclador, y se vierten con palas en el mezclador. A veces sólo se destina, por ejemplo, un palero para el cemento, tres para la arena y seis para la piedra, pero este método es demasiado primitivo para la generalidad de los casos.

**39.** Los mezcladores de cantidades fijas de mezcla dan el concreto en porciones, cuya magnitud depende de la capacidad del mezclador. Tienen un alcance más amplio que los mezcladores sólo movidos por la gravedad y dan mayor seguridad en la proporción de los ingredientes.

**40.** El mezclador de mezcla por lotes, más antiguo y más sencillo, consiste en una

caja **cúbica** de hierro, giratoria, lisa por dentro, sostenida por sus ángulos opuestos, y provista, por un lado, de una compuerta corrediza, para dar entrada á los materiales y descargar el concreto. Aplícase la fuerza del vapor por medio de un engranaje en el eje. Los ingredientes pueden mezclarse secos por un número de vueltas, y el agua se agrega después por medio de los huecos de los muñones, ó puede agregarse el agua antes de hacerse la mezcla. Los mezcladores cúbicos más antiguos tenían que detenerse tanto al cargar como al descargar el concreto.

**41.** En *Superior Entry*, Wis., el Gobierno de los Estados Unidos usó un mezclador cúbico de concreto, que cargaba y descargaba sin detenerse y sin variar la velocidad. Era movido por una máquina de vapor vertical simple de 18×25 cm y daba en 80 segundos un concreto perfectamente mezclado. El concreto se veía durante todo el proceso.

**42.** En más modernos mezcladores por lotes, la caja cúbica es reemplazada por **un tambor** (ó cilíndrico ó caja formada de dos conos), que se hace girar por medio de una cadena en un anillo que rodea el tambor, y provisto de aletas fijadas en su interior. Estas aletas elevan primero y después vierten el material, mezclándolo por la agitación que producen. La descarga se efectúa, en la máquina de doble cono de Smith, inclinando la máquina (como un convertidor de acero de Bessemer) sobre sus muñones, colocados en el centro de gravedad del tambor; y, en la máquina de tambor cilíndrico de Ransome, insertando una artesa de volteo, que, en la posición de descarga, toma el material como cae de las aletas.

**43.** Para remediar **las rupturas**, cada mezclador debe estar siempre provisto de **piezas de repuesto**.

**44. Montaje.** Los mezcladores son ó estacionarios, ó montados sobre rodillos ó carros con ruedas, con ó sin máquina de vapor, máquina de gasolina ó motor eléctrico.

**45.** El mezclador, con su armazón, es levantado á veces completamente desde su primera posición y llevado á otra, por una grúa ó vía de cable.

**46.** Se han usado **mezcladores de concreto con ruedas** y con tambores giratorios, en que se cargan los ingredientes, y se mezclan por el movimiento del vehículo al andar. La fuerza motriz puede darse á brazo, por fuerza de sangre ó por máquina de gasolina; y la relación entre la velocidad hacia adelante y la velocidad de rotación puede regularse por un engranaje.

**47.** Se venden pequeños mezcladores de cantidades fijas de mezcla para moverse á brazo, con capacidad del 13 m cúb por día.

**48.** En la **elección de un mezclador**, es de primera importancia la confianza, debida á que se haya usado con buen éxito, especialmente cuando se necesita un trabajo continuo.

**49.** La reducción del producto puede ser debida á **falta de fuerza** motriz del mezclador ó al mezclador mismo.

**50.** El mezclador **debe limpiarse** después de cada día de trabajo.

## COLOCACIÓN

**51.** El mejor concreto puede hacerse de muy poco valor por falta de cuidado ó método en su colocación.

**52.** Cuando el concreto se **descarga de una altura considerable**, parece que hay riesgo de que se altere la igual distribución de los materiales. En consecuencia, si se baja en baldes, éstos deben llevarse cerca del trabajo ya hecho, antes de voltearlos. Sin embargo, en la construcción de las pilas de concreto para un puente en Bethlehem, Pa., por Cramp and Co (E. R, '09/marzo/6, pág. 280), el concreto se descargaba por medio de una canal inclinada de madera, forrada con palastro, en un punto que quedaba verticalmente á 23 m debajo del mezclador; el método resultó económico, el concreto uniformemente bueno, y no hubo dificultad por separación de los ingredientes.

**53.** En obra que haya de ser de apariencia, las **capas** se limitan ordinariamente á cosa de 15 cm de grueso, debido á la dificultad de aplanar el paramento con el reverso de las palas cuando las capas son más gruesas; pero en cimientos y en obras pesadas, sobre el suelo, si ha de revestirse con mampostería, ó, si la apariencia no es de importancia, pueden usarse capas de concreto húmedo hasta de 60 cm de espesor.

**54.** Si el concreto, después de colocado, está **demasiado húmedo**, es mejor corregir el inconveniente colocando sobre él concreto más seco. Cuando se **le saca el agua excedente**, con ella se saca algún cemento que se desperdicia.

**55. El exceso de aplanamiento con las palas** hace subir el agua de abajo, y ésta lava el cemento del paramento.

**56. Las obras de considerable longitud**, tales como represas y muros, se construyen comúnmente en secciones alternativas, así: las secciones 1, 3, 5, etc., se construyen primero separadamente, y, cuando se han endurecido, se construye la sección 2 entre las secciones 1 y 3, la sección 4 entre las secciones 3 y 5, etc. Los lados de las secciones 1, 3, 5, etc., sirven así como parte de las hormas para las secciones 2, 4, etc. Este método facilita la trabazón entre las secciones, por medio de ranuras y ensambladuras verticales, formadas, por los moldes, en los lados de las secciones construídas primero. El concreto de las secciones restantes, colocado más tarde, entra en estas ranuras y las llena.

**57. En tiempo de helada** puede colocarse el concreto en grandes masas en agua ó debajo de la superficie del suelo. En las excavaciones, si se permite que el agua del suelo se eleve por sobre la obra durante la noche, ordinariamente impedirá que la helada llegue al concreto.

**58.** En la represa de la caída de agua, en Chaudière, se colocó concreto en **temperaturas muy bajas** (como — 29° C). Se erigió una casa para hacer mortero, y la temperatura interior se mantuvo, por medio de estufas, más alta que la de congelación. Los materiales se bajaban á la casa por grúas al través de escotillas hechas en el techo. Guardábase el agua en pipas y se mantenía tibia con chorros de vapor. La arena se calentaba fuera de la casa. La piedra, en pilas de 1 á 1.20 m de alto, se calentaba (pero no se secaba) por chorros de vapor de un tubo perforado que pasaba por debajo de las pilas. Después de colocado, se cubría el concreto suelto con lona, bajo la cual se introducía la boca de una manguera de vapor.

## Tapialeras y armaduras.

**59.** En los cimientos para muros, la zanja misma puede constituir la armadura; y en represas y arcos de bloques de concreto, los primeros bloques, colocados alternativamente, sirven á menudo como partes de las armaduras para los bloques restantes; pero de ordinario se requiere considerable cantidad de armazón de madera. Véase § 56.

**60.** La economía de la obra depende en tan gran parte del **diseño** de las armaduras, que á menudo es conveniente modificar el diseño de la obra misma, ó usar más concreto que el que de otro modo sería necesario, para conseguir economía en aquéllas. El diseño debe ser tal, que puedan usarse los tamaños corrientes de madera con un mínimo de desperdicio; y además que las armaduras puedan fácilmente levantarse y quitarse con el mínimo daño para ellas y ninguno para la obra, y usarse varias veces. Cuando sea posible, las armaduras se hacen en secciones, suficientemente pequeñas para ser movidas con comodidad y manejadas separadamente. El corte se hace económicamente con máquinas de aserrar.

**61.** Aun en trabajo de edificación, donde muchas veces hay que construirlas en su lugar, y donde sólo pueden mudarse quitándolas por partes, la madera puede usarse dos ó tres veces antes de ser desechada. Cuando las armaduras pueden reunirse en **secciones**, y éstas mudarse en un solo cuerpo pueden usarse muchas veces.

**62.** Las exigencias de diferentes obras, ejecutadas bajo diferentes condiciones, varían tanto, que, dentro de los límites de que disponemos, no podemos dar pormenores útiles sobre la construcción de las tapialeras, moldes, armaduras, etc., excepto para edificios. Véanse §§ 63, etc.

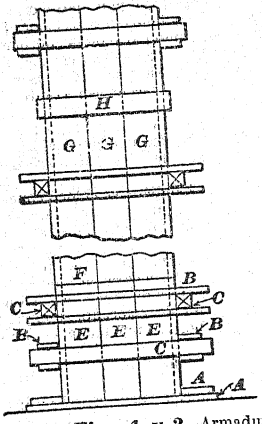
## Armaduras para edificios.

**63. En la construcción de edificios de cemento armado**, las armaduras son principalmente:

(*a*) Armaduras para columnas;
(*b*) Armaduras para vigas, planchas, pisos y techos;
(*c*) Armaduras para muros.

**64. Armadura** típica **para columna**, figs. 1 y 2. Las tablas, G, 3 cm de espesor, se sostienen por listones, H, de 3 12 cm y por abrazaderas, C, de piezas de 10 10 cm, y tablas, B, de 3 12 cm. Estas abrazaderas deben estar separadas para soportar la presion producida por el concreto. Al pie de una columna de 5.50 m de alto, deben estar a de 25 cm de centra a centro. En el fondo se ponen 4 tablas, A, para mantener la armadura vertical, y las tablas, G, se cortan, en un lado de la caja, en F, á 60 ó 90 cm del fondo, para formar una puerta los listones que cierran

la puerta no se ven) por la cual pueden barrerse todas las basuras. La puerta se mantiene entonces cerrada por las dos abrazaderas inferiores, y se llena la armadura. Usanse filetes triangulares, T, para hacer en bisel los ángulos de la columna.



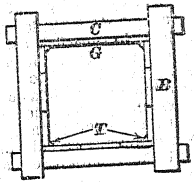


Fig. 2.

**Figs. 1 y 2.** Armadura para columna.

**65.** Las armaduras para columnas deben hacerse de manera que puedan quitarse sin perturbar las armaduras para las vigas. Así se pueden descubrir las armaduras de las columnas para inspeccionarlas antes de cargarlas.

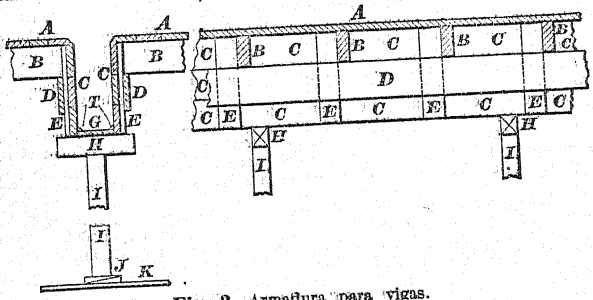

**Fig. 3.** Armadura para vigas.

**66. Armaduras típicas para vigas,** fig. 3. Las armaduras, ó cajas para vigas, se sostienen, entre columnas, por puntales temporales, I, de 10×10 cm, distantes entre sí como 1.80 m y descansando sobre cuñas, J, y tablas, K. Colócanse modillones, H, de 4×4 pulgadas, directamente debajo de los fondos, G (3 cm de grueso) y de los lados, C (3 cm de grueso) de las cajas de las vigas. Los lados, C, se mantienen unidos por listones de refuerzo, E de 3×12 cm y 60 cm distantes entre sí, á los cuales están clavados los listones, D (3×15 cm), sobre los cuales descansan las traviesas, B, de 5×15 cm, y más ó menos separadas 70 cm. Éstas sostienen la tablazón, A, de 3 cm de grueso, y ésta, á su vez, sostiene las planchas. Pequeños filetes triangulares, T, en los ángulos de las cajas de viga, cierran las rendijas de la caja y forman ángulos biselados. A las armaduras de viga debe dárseles una ligera curvatura.

**67. Las armaduras** típicas **para pisos** entre vigas de acero, figs. 4 á 6, varían con la luz y la carga. Las armaduras se cuelgan del reborde de la base de las vigas en I, por « pernos colgantes », A, figs. 4 y 6, de 15 mm de diám, con arandelas y tuercas. Estos pernos aseguran las piezas, E, de 5 × 10 ó 7½ × 10 cm, sobre las cuales descansan las tablas, HHH, sostenidas por traviesas de 5 × 15 ó 5 × 20 cm, D

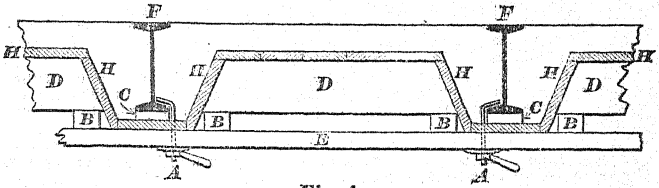

Fig 4.

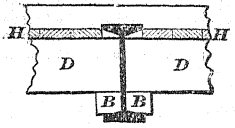

Fig 5.

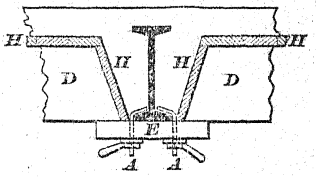

Fig 6.

**Figs. 4, 5 y 6.** Armaduras para pisos.

(colocadas como á 70 cm de centro á centro, para tablas de 2 cm). A veces se colocan bloques ó cuartones de madera, B, figs. 4 y 5, debajo de las traviesas para reducir su altura. Usanse bloques cortos de concreto, C, fig. 4, para mantener las armaduras separadas del reborde inferior de la viga de acero. Éstos quedan permanentemente en la obra. Para fomentar la adhesión entre los rebordes inferiores de las vigas en I y la masa delgada de concreto debajo de ellas, envuélvense á menudo los rebordes con tiras metálicas antes de colocar los bloques, etc.

**68. Las armaduras para muros** se hacen de ordinario en secciones, para que puedan usarse varias veces. Las secciones van ligadas entre sí por listones de refuerzo y de ordinario son de unos .90 × 3.60 m. Las secciones se mantienen separadas á la distancia conveniente por separadores de madera ó concreto, y se mantienen en posición por pernos ó ligaduras de alambre. Cuando se usan separadores de madera, deben retirarse precisamente antes de la colocación del concreto. A veces se usan separadores de bloques ó tubos de concreto. Éstos quedan en el muro. Cuando se emplean pernos que han de retirarse más tarde y usarse otra vez, deben aflojarse por medio de una llave inglesa, como 24 horas antes de colocar el concreto; de otro modo será difícil retirarlos.

**69.** En el sistema **Wiederholdt** de construcción de muros de cemento armado, se deposita el concreto dentro de bloques huecos hechos con pequeñas baldosas que van á formar el paramento exterior, y no se usan armaduras de madera ú otras temporales. Estas baldosas tienen la forma requerida para la obra. La colocación del concreto y la de las baldosas se hace simultáneamente.

**70.** Para reducir el costo de las armaduras en la construcción de edificios de cemento armado, pueden **modelarse en el suelo** las columnas, vigas, planchas, etc., y colocarlas luego como se desee; sacrificando, sin embargo, la rigidez producida por el carácter monolítico de las obras ordinarias de cemento armado.

**71. Armaduras de metal.** Cuando la estructura consta de secciones transversales pequeñas y uniformes, que permitan el uso repetido de las mismas armaduras, como en albañales, canales, túneles, etc., las cubiertas de las armaduras de madera pueden ser de láminas metálicas. En los túneles y obras semejantes, de considerable extensión, y en obras ornamentales pequeñas, pueden usarse armaduras compuestas enteramente de metal.

**72.** Ha de evitarse tanto el **alineamiento** descuidado como el demasiado

esmerado. El Sr. W. J. Douglas (E. N. '06 /Dic. /20, pág. 646) insinúa la concesión de 1 cm de discrepancia de las líneas establecidas en obras « acabadas », de 5 cm en las otras.

**73. Evítense detalles delicados** y los ángulos agudos. Los ángulos deben redondearse ó biselarse, para facilitar el curso del concreto y el retiro de las armaduras, y para que los ángulos estén menos expuestos á daños subsiguientes.

**74. Las armaduras de madera**, dentro de las cuales ha de ponerse el concreto, deben ser bastante impermeables, lisas y de suficiente fuerza y rigidez para conservar sus líneas bajo la presión del concreto fresco.

**75.** Las armaduras se hacen por lo común de madera de tamaños corrientes, cubiertas con tablas ó planchas acepilladas. La abertura de las juntas entre las planchas puede evitarse parcialmente empleando tablas ensambladas (machihembradas).

**76.** El mortero, que se exuda por las aberturas, deja huecos en la superficie. En consecuencia, en armaduras para obras de paramento, las **juntas deben hacerse impermeables**, si fuese necesario, con mortero, masilla, yeso, papel de forro ó metal delgado.

**77.** Si la madera está muy seca, su hinchazón, debída á la humedad, puede torcer las tablas y producir una obra fea. En tales casos, las tablas no deben ser ensambladas, sino que deben tener los bordes ligeramente biselados y los ángulos agudos de los bordes de las tablas adyacentes deben ponerse en contacto. La hinchazón aplastará los bordes antes que torcer la tabla.

## Madera para armaduras.

**78.** El pino blanco es el mejor para paramentos delicados y muy útil en construcciones ornamentales cuando se hacen con armaduras de madera.

**79.** El abeto, el pinabete, el pino de Noruega y las clases más blandas de pino del Sur son más susceptibles de cimbrarse que el pino blanco, pero son generalmente más rígidas y por tanto mejores para refuerzos y puntales.

**80.** La madera parcialmente seca es generalmente la mejor. La madera secada al horno es inapropiada, pues se hincha al contacto con el concreto húmedo. Con madera muy verde, especialmente el pino del Sur, pueden abrirse las juntas. La madera verde es pesada y no sostiene bien los clavos.

**81.** Para armaduras de tablero para muros, la madera machihembrada ó de bordes biselados es preferible á la de bordes cuadrados. La machihembrada da una superficie más lisa y menos aberturas de las juntas que la de bordes cuadrados ó biselados, pero es más costosa, á causa del desperdicio al labrarla, y hay más desgaste en las juntas si las armaduras se usan con frecuencia.

**82.** Aun para armaduras ordinarias, el acepillado por un lado puede ahorrar dinero reduciendo el costo de limpieza después del uso. Los puntales deben estar siempre acepillados por un lado para ajustarlos á las medidas.

**83. Espesor.** Para muros ordinarios, 4 cm; para construcciones pesadas, en que se emplean grúas, 5 cm. Para secciones de pisos son muy usadas las tablas de 2.5 cm; pero, en edificios altos, se deterioran mucho y producen un « mal acabado » en las caras inferiores de los pisos. Para lados de vigas bastan 2.5 á 4 cm, pero para fondos son mejor de 5 cm. Las armaduras para columnas son generalmente de tablones de 5 cm.

**84.** Los parales son generalmente de $7\times10$ á $10\times15$ cm; $10\times10$ es el tamaño más útil. La distancia es de ordinario 60 cm para tablas de 2.5 cm, 1.20 m para 4 cm (espesor), 1.50 m para 5 cm.

**85.** Puesto que las vigas y las columnas soportan fuerzas mayores que las planchas de piso, sus armaduras deben dejarse en su lugar mayor tiempo y por tanto deben ser independientes de las armaduras del pavimento, etc.

**86.** Los lados de las armaduras de las vigas deben calzarse entre sí para impedir que se separen de las tablas del fondo, bajo la presión del concreto.

**87.** Las cuñas de madera dura, en los topes y las bases de los puntales, facilitan la colocación y la remoción de aquéllos y las pruebas de flexión.

**88. Las piezas livianas** (digamos de $5\times20$ ó $5\times25$), con frecuentes puntales, son preferibles á tamaños más pesados, difíciles de manejar.

## Fuerza de las armaduras.

**89. La fuerza** requerida para las armaduras puede calcularse, cuando se usa concreto húmedo, suponiendo la presión del concreto igual á la de un líquido que

pese unos 2,400 kg por metro cúb *. Si se usa concreto seco y apisonado fuertemente, la acuñada de la piedra con el pisón aumentará considerablemente la presión.

**90. Cargas permitidas** en kg, sobre puntales de madera para construcción de pisos.

| Longitud sin soportes, metros. | Sección trasversal de puntales, centímetros. | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | 7.5×10=75 | | 10×10=100 | | 15×15=225 | | 20×20=400 | |
| | Por cm cuad. | Total. | Por cm cuad. | Total. | Por cm cuad. | Total. | Por cm cuad. | Total. |
| | kg. | kg. | kg. | kg. | kg. | kg. | kg. | kg. |
| 4 | | | 49 | 4900 | 63 | 14175 | 77 | 30800 |
| 3.50 | 42 | 3150 | 56 | 5600 | 70 | 15750 | 84 | 33600 |
| 3 | 49 | 3675 | 63 | 6300 | 77 | 17325 | 84 | 33600 |
| 2.50 | 59.5 | 4462 | 735 | 7350 | 84 | 18900 | 84 | 33600 |
| 1.80 | 70 | 5250 | 84 | 8400 | 84 | 18900 | 84 | 33600 |

**91.** En vigas de madera, calculadas para resistencia, la **resistencia de la fibra extrema** ha de calcularse en 52.5 kg por cm cuad.

**92. La carga viva durante la construcción**, mientras el concreto fragua, es de 366 kg por m cuad en las planchas, 244 por m cuad al calcular las vigas para las armaduras. Esto incluye el peso de los hombres, carretillas llenas de concreto y material de construcción depositado en el piso, pero no montones de cemento, arena ó piedra, que no se deben permitir á menos que se tenga en cuenta su peso.

**93. Las armaduras para pisos** deben basarse en la flexión **permitida** más que en la resistencia. Fórmula :

$$d = \frac{3WL^3}{384\,EI}; \qquad I = \frac{bh^3}{12}$$

en que

$d$=flexión;
W=carga total sobre tablazón ó vigas;
L=distancia entre soportes;
E=módulo elástico de la madera empleada;
I=momento de inercia de la sección transversal de la tablazón ó viguetas;
$b$=ancho de la tablazón ó vigueta;
$h$=altura de la tablazón ó vigueta.

En la fórmula usual para flexión (véase pág. 503) $^1/_{384}$ es el coeficiente para viga con extremos fijos, mientras $^5/_{384}$ es el coeficiente para extremos apoyados solamente.

Peso del concreto, inclusive refuerzo, 2,400 kg por m cúb.

(Sanford E. Thompson, Boletín 13 de la Asociación de Fabricantes de cemento.)

## Detalles de las armaduras.

**94.** Demasiados **clavos** aumentan la dificultad de desarmar las armaduras sin dañarlas. Los clavos punta de París pueden sacarse con menos daño para la madera que los clavos angulares.

**95.** Los tirantes de hierro ó acero, que se extienden al través del muro y mantienen las armaduras en posición, de ordinario se vuelven á usar si tienen $>$ 6 mm de diámetro. Si $\not>$ 6 mm de diámetro, se dejan generalmente; pero, si sus extremos llegan á la superficie exterior del muro, producen manchas feas de oxidación. Para impedir esto, se rebaja el concreto que rodea sus extremos y se recortan las puntas de las varillas. Los huecos que quedan se llenan después con mortero.

* El Sr. W. J. Douglas (E. N., '06/dic /20, pág. 646), considera al concreto como un líquido de la mitad de su propio peso, de 1,200 kg por m cúb.

**96.** A veces se emplean **separadores** (patentados por Wm. T. McCarthy, 1 Madison Ave., ciudad de Nueva York) hechos de cemento, en forma de cilindros huecos y de 10 á 15 cm de largo que rodean los pernos. Después de separado el perno, se llena con mortero el hueco del cilindro.

**97.** Las armaduras pueden sufrir por los golpes del balde de concreto, ó por el movimiento de las máquinas en contacto con ellas.

**98.** Todo concreto que se adhiera á una armadura debe quitarse antes de que ésta vuelva á usarse.

### Adhesión á las armaduras.

**99.** Si la madera es nueva, y si las armaduras se mojan perfectamente antes de colocar el concreto, éste, si está duro, no se adhiere á las armaduras cuando se retiran. Si han de retirarse las armaduras antes de que el concreto endurezca, deben, antes de colocarse el concreto, ser engrasadas con una substancia bastante delgada que corra y penetre en la fibra de la madera; se emplea el aceite crudo, el aceite de linaza, el jabón blando y otros lubricantes.

**100.** Una obra nueva puede adherirse á las maderas viejas, en que se ha adherido concreto anteriormente, aunque éste se haya limpiado.

**101.** El aceite, aplicado á las armaduras (para impedir su absorción de agua ó para facilitar su retiro, § 99), puede penetrar en las juntas entre la obra vieja y la nueva é impedir la formación de una adherencia satisfactoria. El **jabón** es por supuesto inocuo en este caso.

### Retiro de las armaduras.

**102.** La **prematura** remoción de las armaduras y los puntales ha causado **muchos fracasos** en edificios de concreto; pero el indebido retardo en su retiro significa retardo en la obra y aumento del número de armaduras.

**103.** La ley francesa requiere que los **bloques de prueba** y vigas de ensayo sean hechos para cada sección que se construye. Éstos permiten al ingeniero juzgar las condiciones de la obra.

**104.** Los **puntales** deben retirarse de **una sola viga** ó pieza á la vez y deben reemplazarse inmediatamente después que se han retirado las armaduras para esa viga. Esto permite descubrir y reparar los defectos.

**105.** Las **armaduras pueden retirarse más temprano** en tiempo cálido y seco que en tiempo frío y húmedo; más temprano cuando las cargas son ligeras que cuando son pesadas; con cemento de fragua rápida que con cemento de fragua lenta; con mezclas secas que con mezclas húmedas. (Véase Especificaciones, pág. 1409.)

**106.** Para aliviar **las cajas de vigas**, pueden apoyarse los postes sobre cuñas y ponerles una tabla arriba. Los postes y sus capiteles no se deben retirar de más de una viga á la vez. Después que se havan retirado las cajas de las vigas, deben reemplazarse los postes y las tablas antes de retirarse las armaduras de cualesquiera otras vigas; ó los postes pueden estar apoyados sólidamente y con una plancha de apoyo que forme el fondo y sostenga las tablas laterales de las cajas de la viga. Las tablas laterales pueden retirarse entonces, dejando sin mover los postes y planchas de apoyo.

**107. Los esfuerzos que obren como palancas contra el concreto**, al retirar las armaduras, pueden dañarlo.

### Juntas en el concreto.

**108. Dificultades.** En las obras grandes, las juntas, entre obras hechas en diferentes días, y aun antes y después de una hora de intervalo, pueden presentar inconvenientes, sobre todo donde se requiere impermeabilidad.

**109. Causas.** La dificultad parece deberse en parte á una nata ó película superficial del concreto endurecido, y en parte á la presencia de materiales aceitosos ó eflorescencias y suciedades, entre las dos superficies. El aceite empleado en las armaduras, ó contenido en la ropa de los trabajadores, puede llegar hasta las juntas. El aserrín es particularmente difícil de quitar. La unión es sobre todo débil si la superficie más vieja está helada.

**110. Remedios.** Muchos remedios se han propuesto, anunciado y usado, pero ninguno ha sido bien probado. Véase Especificaciones, pág. 1408. Los mejores preventivos son, probablemente, la limpieza de la superficie y el uso de mezclas húmedas. El agua, usada en lavar las juntas, debe ser limpia. Un chorro de vapor vivo de alta presión es muy eficaz, pues quita hasta el aserrín. Usase con éxito el

ácido hidroclórico. Los métodos patentados para asegurar la unión de las juntas, incluyen el uso de ligazones metálicas, saliendo sus extremos de la superficie más vieja, para trabar con la nueva. En otro método se emplea una capa de escoria esparcida sobre la superficie más vieja, cuando está aún blanda, quitándose la escoria suelta después del endurecimiento de la superficie más vieja, antes de colocar el material nuevo.

**111.** Cuando el concreto se usa para **reforzar** y proteger **una mampostería vieja**, debe quitarse una piedra aquí y allá de la mampostería vieja, y limpiarse y lavarse las juntas. Pueden también introducirse pernos grandes con grandes arandelas en las cabezas para que entren en el nuevo concreto. El concreto debe también penetrar bastante hacia el interior del muro para impedir que el agua entre en las juntas horizontales por encima de los muros laterales y de los muros principales.

## Apisonado.

**112.** El **apisonado** del concreto es sólo necesario en las mezclas relativamente secas. Cuando se hace bien, consolida la masa, cosa de 5 ó 6%, haciéndola menos porosa y considerablemente más fuerte. Para apisonadores, véase Especificaciones, pág. 1407. Los hombres que los usan, si están sobre el concreto, deben llevar zapatos de caucho.

**113. Debajo del agua** el apisonado sólo puede hacerse parcialmente y cuando el concreto está contenido en sacos. Puede usarse un rastrillo con suavidad para nivelar el concreto suelto depositado debajo del agua.

**114.** El apisonado debe suspenderse antes de empezar la fragua. El apisonado excesivo destruye la homogeneidad del concreto.

## Colocación debajo del agua.

**115. El concreto puede depositarse fácilmente debajo del agua.** Comúnmente se baja, poco después que se mezcla, en un balde de dragar ó en una caja de madera ó de palastro en forma de V, con una tapa que pueda cerrarse mientras desciende la caja. La tapa se omite á menudo. Esta caja está dispuesta de tal manera, que, al llegar al fondo, pueda halarse un perno por una cuerda que llega á la superficie, permitiendo así que uno de los lados inclinados se abra y deje caer el concreto. Entonces se eleva la caja para llenarse otra vez. En obras grandes la caja puede contener un metro cúbico ó más y debe estar suspendida de una grúa movible, por la cual pueda llevarse á cualquier punto de la obra. El concreto puede nivelarse suavemente, si fuere necesario, con un rastrillo, poco después que sale de la caja. Su consistencia y su fuerza desminuirán naturalmente si se sale de la caja y cae al través del agua; y además, no puede apisonarse debajo del agua sin dañarlo aún más. De la manera arriba expresada se ha depositado en profundidades de 15 m.

**116.** A veces se usa para depositar concreto debajo del agua una caja de madera ó de palastro, redonda ó cuadrada, abierta arriba y en el fondo, y de un largo apropiado á la profundidad del agua. Puede tener unos 45 cm de diámetro. Su parte superior, que siempre se mantiene sobre el nivel del agua, es en forma de tolva, para recibir más fácilmente el concreto. Se mueve lateral y verticalmente por una grúa ú otro aparejo apropiado. Al comenzar las operaciones, se apoya su extremo inferior en el fondo del río, llénase primero enteramente de concreto, el cual (para impedir que sea arrastrado en pedazos cayendo al través del agua en la caja) se baja en una cuba cilíndrica, con un fondo semejante á la caja descrita en el § 115, que puede abrirse cuando llega á lugar conveniente. Llena, la caja se mantiene así con el nuevo concreto, que se vierte en la tolva para ocupar el lugar del que gradualmente cae abajo, pues la caja se levanta siempre un poco para que el concreto vaya saliendo. El peso de la caja llena va compactando el concreto á medida que se deposita. Es mejor que la caja sea más ancha abajo para que facilite la salida del concreto.

**117.** El área sobre la cual se va á depositar el concreto debe rodearse previamente por alguna especie de valla, para impedir que el concreto se esparza fuera de sus límites, y para servir de molde á la forma deseada. Consiste generalmente en una caja de madera ó de palastro sin fondo que queda en la obra. Si es de madera puede requerir una fila de cajones adyacentes, exteriores, que se llenan de piedra ó cascajo para sumergirla. Debe evitarse el escape del concreto por espacios abiertos debajo de los lados de la caja ó valla. Para esto puede hacerse la caja de modo que se adapte á las desigualdades del fondo, cuando éste no pueda fácilmente nivelarse. A veces es mejor el empleo de láminas de palastro al interior, ó fijar afuera ó adentro una faja de encerado, en todo el contorno del borde inferior de la caja, pisándola a

con piedra ó cascajo para mantenerla en su sitio sobre el fondo. Piedra rota ó cascajo y aun tierra (las dos últimas donde no hay corriente) amontonados fuera de una caja débil, impedirán que se combe hacia afuera por la presión del concreto. Después que se haya subido el concreto hasta algunos pies del nivel más bajo del agua y ya nivelado, podrá comenzarse la mampostería sobre él por medio de un cajón (*caisson*) fijado ó empleando hombres con escafandras. O, si el concreto llega muy cerca del nivel menor del agua, puede echarse una primera camada gruesa de piedra, y ponerse así la obra desde luego sobre dicho nivel sin necesidad de aquellos recursos.

**118. El concreto debe extenderse** de .60 á 1.50 m (según el caso) fuera de la base de mampostería. Todo el lodo debe quitarse antes de depositar el concreto.

**119.** En algunos casos se usan **sacos llenos en parte de concreto** y simplemente arrojados en el agua. Si el tejido de los sacos es ligeramente abierto, parte de la pasta de cemento se sale y une el todo en una masa tolerablemente compacta. Tales sacos se emplean, con la ayuda de buzos, para coger filtraciones, apuntalar cimientos, y varias otras obras. Los sacos de cemento pueden apisonarse hasta cierto punto.

**120. Puede colocarse encerado sobre las grietas de la roca** para impedir la pérdida del concreto; y, en algunos casos, para impedir que sea arrastrado por la corriente.

**121.** El concreto debe colocarse en agua, en **grandes lotes**, á fin de que la proporción entre la superficie expuesta y el volumen sea pequeña. En agua corriente, desvíese el curso con tubos ó canales ó por medio de diques (para lo cual es apropiado el concreto en sacos). Si se extrae agua del pozo mientras se pone concreto, puede ella llevarse el cemento. Obsérvese el agua que sale de la bomba para saber si hay pérdida de cemento.

**122.** Los cimientos de diques de concreto sobre roca de 4 á 6 m debajo del menor nivel del agua, y si están cubiertos de lodo, se colocan con la ayuda de buzos, quitando el lodo por medio de chorros. No se nivela la roca. Se construyen las armaduras sobre la roca y se llenan los vacíos que queden debajo de aquéllas con sacos de concreto. Las armaduras se mantienen debajo del agua por medio de cajas llenas de piedra, y se anclan con cables de alambre cerca del fondo, en pilotes cercanos y reforzados arriba, con crucetas clavadas al dique existente. El concreto se baja por grúa, en baldes como de ½ m cúb que se descargan por el fondo cuando está cerca de la obra. El único cemento perdido es la poca cantidad que barre el agua en la parte superior del balde cuando se sumerge. La obra debe presentar caras lisas á lo largo de las armaduras y aparecer perfectamente homogénea. (E. R., '05/oct./21 pág. 468.)

**123.** Colocación de concreto, **bajo 27 m de agua**, en un pozo. Para detener la entrada del agua en el fondo de un pozo, se lleva el concreto, por una tolva, á un tubo de hierro forjado de 20 cm con uniones de tornillo, cuyo extremo inferior está cerrado con un tapón de madera y descansa en el fondo del pozo. Cuando el tubo se levantaba ligeramente, el tapón no salía y no descargaba el concreto. Retirado el tubo y desarmado, se vació cada sección. El tapón, que no estaba apretado, había dejado que la sección más baja se llenase de agua, y se desintegraba el concreto, dejando, en el tope de la sección más baja, un tapón de cemento puro que impedía, como se deseaba, al concreto de arriba expulsar el tapón de madera. Se repitió el ensayo con un tapón apretado. Dentro del tubo de 20 cm se colocó un tubo de 4 cm, por medio del cual se expulsaba el tapón de madera, dejando bajar el concreto. Se regularizó la descarga cambiando la distancia del pie del tubo sobre el fondo del pozo y se depositó una masa de concreto de 3 á 4 m de espesor. Los 15 ó 20 cm superiores nunca fraguaron; pero el resto apareció sólido y homogéneo. (Assn. C. E., Cornell Univ., Trans., 1898, pág. 74.)

**124.** En un caso en que los pilotes de hierro huecos, en fondo arenoso limpio, se llenaron de concreto, parte del mortero se salió y formó, con la arena circundante, masas de concreto que se adhirieron tenacísimamente á los pilotes, sugiriendo el empleo de **pilotes huecos perforados** *ad hoc*, en sus partes inferiores, con huecos pequeños, por los cuales se escapa hacia la arena el mortero delgado vertido por arriba. (Chas. List, Jour. Assn. Engg. Socs., marzo, 1903, vol. 30, n.° 3, pág. 124.)

**125.** *Superior Entry, Wis.* El mezclador se vacía en una tolva inferior provista de una canal de compuerta que á su vez descarga en los baldes que llevan el concreto y que corren en carriles situados debajo de la plataforma. Al llegar á la obra, los bajan á las armaduras sumergidas unas grúas movibles. Cada balde está provisto de dos cubiertas de lona, divididas en dos piezas, forradas en plomo y fijadas á los lados opuestos del balde. Cuando están en su posición, estas piezas se montan unas sobre otras en el medio de los baldes, cubriendo completamente el concreto. Cuando

el balde llega al fondo, se voltea por una aldaba especial provista de una cuerda que tiene el encargado de la grúa. Las cortinas de lona impiden que el agua arrastre el concreto. Un balde cargado pesa como 6 toneladas. El golpe del balde cargado sobre el concreto ya colocado parece compactarlo suficientemente. La descoloración del agua por el cemento, durante el descenso del balde cargado, se nota poco. (Informe del Ingeniero en jefe. E. U. de A., 1904, parte IV, pág. 3785.)

## ACABADO DE LAS SUPERFICIES

**126.** Después de retiradas las armaduras de madera, la superficie de concreto muestra las marcas de la fibra, nudos y juntas de las cubiertas. Esta apariencia puede ser ó no objetable.

**127.** El enlucido con mortero de cemento da un buen acabado en el interior de los edificios, donde la lluvia y la helada no pueden afectarlo, pero ordinariamente se desconcha cuando se aplica á superficies exteriores.

**128.** Las superficies exteriores **pueden ser lavadas con una mezcla delgada de cemento,** después de rellenar las juntas, donde sea necesario, con mortero de cemento. Esto debe hacerse mientras el concreto está nuevo, y, si fuere posible, inmediatamente después de retiradas las armaduras. Una mezcla delgada, compuesta de 1 parte de yeso y 3 partes de cemento, aplicada con brochas de lechada, da resultados satisfactorios.

**129.** Las superficies de concreto pueden ser labradas con un hacha dentada, dando una variedad de efectos. Si se pican cuando el concreto está algo blando, queda una superficie áspera, que muestra la piedra y luce como una obra ordinaria. Si la herramienta no es cortante, daña la superficie. Hanse usado eficazmente las herramientas de aire comprimido y la máquina de lanzar arena se ha empleado con éxito; las primeras en el Stadium de Harvard.

**130. Revestimientos de mortero especialmente preparado,** se colocan á veces al mismo tiempo que el cuerpo del concreto por medio de una lámina metálica puesta de canto. Esta lámina separa el revestimiento del relleno; y cuando el revestimiento y el relleno llegan á cierto nivel, se quita la lámina y vuelve á usarse en la capa que sigue. Después de quitada la armadura se unen el revestimiento semifluido y el relleno en el angosto espacio que ocupó la tapa.

---

**131.** El revestimiento no debe ser más de 1 : 3, salvo para obras de ornamentación, para superficies sencillas, 1 : 4. Un revestimiento demasiado rico y excesiva pulitura tiende á cuartearse y es costoso. En el ferrocarril de Chicago Milwakee y San Pablo, en Chicago, el cemento empleado para poner un revestimiento de 3½ cm fué un mortero de 1 parte de cemento Portland para 2 de arena; se gastó en cemento el 9% del usado en toda la obra.

**132.** « En el caso de muros delgados, á veces no se puede concluir rápidamente la obra por la imposibilidad de hacer el revestimiento bastante ligero, y en todo caso se necesitan dos ó más hombres para mezclar y llevar mortero y atender á su colocación. » (W. A. Rogers, R. R. Gaz, '00 /julio /6, pág. 461.)

---

**133.** Para **proteger el enlucido de la helada** puede colocarse una capa de papel alquitranado por fuera de los parales dejando un espacio de aire, del espesor de los parales, entre el papel y las cubiertas de la armadura. En este espacio la temperatura será de 4° á 5° mayor que la del aire exterior. Esta protección es por supuesto más necesaria en los lados expuestos al viento. (W. J. Douglas, E. N., '06 /dic. /20, pág. 650.)

---

**134.** El cambio de operarios, mientras se ejecuta el trabajo del acabado, puede dar por resultado la pérdida de la uniformidad en el aspecto.

**135. Fregado antes de que fragüe el concreto.** El Sr. H. H. Quimby (Asociación de consumidores de cemento, Procs., 1907) friega la superficie de concreto fresco, antes que se endurezca, con un cepillo y agua, removiendo así la última película, y, con ella, toda impresión que hayan dejado las armaduras descubriendo y limpiando la piedra y la arena del concreto. Unos pases dados con una escoba ordinaria de las usadas en las casas, y una corriente de agua para lavar y enjuagar, bastan; pero una ligera friega adicional mejora el efecto. La necesidad de retirar ligero las armaduras, cuando se emplea este método, exige un esmero

especial para construirlas, aumentando su costo. Cuando se aplica á superficies que forman ángulos, las partículas de arena proyectadas le dan un aspecto áspero. Por esto debe cuidarse de no extender el sistema á aquellas esquinas.

**136.** Un efecto semejante al obtenido por el método del Sr. Quimby puede producirse, después de la fragua, **lavando con una solución ácida**, que se quita luego con un lavado alcalino, seguido de otro con agua. Este método ataca la piedra caliza del agregado.

**137. Los efectos de color** se producen del mejor modo usando agregado del color deseado.

---

**138.** La dificultad para **hacer adherir la pintura al óleo** á las superficies de concreto fresco se debe á la humedad y á la cal libre. Un lavado de ácido diluído en agua neutraliza la cal, pero no es satisfactorio, pues el ácido muriático (hidroclórico) forma sales altamente higroscópicas, tales como cloruro de calcio, y el ácido sulfúrico sólo produce un efecto superficial. Disuélvanse 4.5 kg de carbonato de amoníaco (sales de cuerno-ciervo) en 170 lit de agua y apliquese una vez con una brocha, ó dense varias manos de una solución más débil, ó apliquese con regadera. El amoníaco se desprende y el ácido carbónico forma, con la cal libre, un carbonato insoluble que pronto se seca y endurece. Después de muchas pruebas se encontró que este método es el único que satisface todas las exigencias. El carbonato de amoníaco se conserva, indefinidamente, en vasijas bien tapadas. (Fred. J. Bosse. « Edad del Cemento », '09 /enero, pág. 48.)

---

## PROPIEDADES DEL CONCRETO

**Peso.** Véase Vacíos, pág. 1298, y Densidad, pág. 1299.

**1. Pesos del concreto en kg por metro cúbico.**

**Concreto de piedra quebrada** ó de cascajo, 2,080 á 2,560; ordinariamente de 2,240 á 2,400.

Un pie BM = vol de un sólido de 1 pie en cuadro y 1 pulgada de espesor, = 144 pulgadas cúb = 1 pie cúb /12 = 2.358 litros.

| Peso, lbs /pies cúb.... | 100 | 110 | 120 | 125 | 130 | 140 | 150 | 160 |
|---|---|---|---|---|---|---|---|---|
| Kg /m cúb..... | 1,600 | 1,760 | 1,920 | 2,000 | 2,080 | 2,240 | 2,400 | 2,560 |

| — | de trapa..... | 2,480 — |

Con cemento **natural** es de 64 á 80 kg más liviano por m cúb.

**2.** La unidad de peso varía no sólo con la naturaleza de los materiales, sino también con las proporciones, la consistencia, el grado de compactación, etc.

### Permeabilidad.

**3.** Aun cuando el principal objeto del concreto no es impedir la filtración por el agua, la impermeabilidad es de grande importancia para aumentar la durabilidad del concreto, y especialmente para proteger á la armadura metálica de la oxidación y de la pérdida de adhesión con el concreto.

**4.** El agua pasa á través del concreto, etc., tan lentamente, que la evaporación del exterior, más rápida, puede hacer que el muro aparezca **seco en el exterior** cuando aún se esté verificando la filtración en el interior.

**5.** Cuando se coloca en mortero endurecido y bien comprimido con la cuchara en todas las superficies que entren en contacto con agua, el **cemento puro** es tan **impermeable** como la mejor de las rocas naturales usadas para construcciones. Wm. B. Fuller, Trans., A. S. C. E., vol. 51, págs. 133-4, dic. 1903.)

---

**6.** El mortero, ó concreto, proporcionado de modo que se obtenga **la mayor densidad posible**, y mezclado un tanto húmedo, es impermeable en condiciones ordinarias.

**7.** Se ha encontrado repetidas veces que pequeños bloques de concreto, hechos cuidadosamente de materiales de tal modo proporcionados que aseguren gran densidad, ó con un exceso de cemento, son tan impermeables como las mejores piedras naturales. Véase Experiencias y práctica, pág. 1349.

**8.** En **grandes masas**, es difícil producir una estructura absolutamente impermeable sin la adición de un revestimiento de material de mayor impermeabilidad que el concreto. Las variaciones en la mezcla, el descuido en la manipulación ó la colocación, ó en la unión de obras hechas en diversos días (la interrupción del trabajo de una hora, en el medio de un día caluroso), ha causado filtraciones. La insuficiencia de agua hará también permeable el concreto á pesar de la apropiada proporción teórica y la adición de cal. La mezcla debe ser por lo menos bastante húmeda para que se asiente con poco apisonado.

**9.** El concreto, impermeable en sí, puede presentar grietas por las cuales penetre el agua. Con refuerzos bien colocados se impiden las grietas.

**10.** El agua puede penetrar al través del mortero, de los elementos del agregado, ó entre el mortero y el agregado. Probablemente la mayor parte de las filtraciones se efectúan al través del mortero. Véase Mortero. Aquí tratamos de aquellos aspectos de la permeabilidad que pueden estudiarse mejor tratando el concreto como un material compuesto.

**11.** Cuando la filtración consiste en simple filtración al través de los **pequeños poros** del concreto, etc. (esto es : cuando no hay verdaderas grietas), disminuye generalmente con el tiempo, pues el agua (aunque aparentemente clara) obstruye su propio paso depositando en los poros del material, ya su propio sedimento natural, ya la cal y otros compuestos disueltos en el concreto mismo.

**12.** Esta acción depende de muchos factores, notablemente de la presión, de los tamaños y formas de los poros, de la dureza y solubilidad del material, y la naturaleza del sedimento arrastrado por el agua. Así, bajo alta presión, si el material es fácilmente lavable, ó si los poros son anchos y relativamente rectos, el derrame puede aumentar, en vez de disminuir, con el tiempo.

**13.** Cuando lo permite la naturaleza del caso, como en pisos, muros de sostenimiento, etc., es mejor desviar el agua por desagües apropiados que tratar de cerrarle el paso haciendo impermeable la estructura.

**14. Cuando se requiere impermeabilidad**, como en represas, deben proporcionarse cuidadosamente los materiales para el máximo de densidad; debe haber un exceso de mortero rico en cemento sobre el vol de los vacíos, y deben evitarse mezclas secas; la mezcla debe ser perfecta y la construcción, hasta donde sea posible, debe ser monolítica.

**15.** La aplicación de **materiales que producen** impermeabilidad puede ser ó (*a*) interna, mezclados con los ingredientes del concreto; (*b*) superficial, llenando los poros cerca de la superficie; (*c*) externa, impidiendo el contacto entre el agua y el concreto.

**16. Interna.** Para obra impermeable, el vol de mortero debe ser de 40 á 45% del vol de agregado, ó de 40 á 42% si el agregado se ha graduado. (Geo. W. Rafter, Trans., A. S. C. E., vol. 42, pág. 149, dic. 1899.)

**17.** Con agregado que tenga 35% de vacíos, el vol de mortero debe ser $<$ 50% del vol de agregado; el vol de arena seca y cemento $<$ ⅔ del vol de agregado; el vol de arena $>$ 2× vol de cem. Para cemento que deje $>$ 10% en tamiz n.º 120, arenas ordinarias, y agregado con 35% de vacíos, se dan las siguientes proporciones

| cemento | arena | agregado | (arena + agreg) ÷ cem. |
|---|---|---|---|
| 1 | 1.0 | 3.00 | 4.00 |
| 1 | 1.5 | 3.75 | 5.25 |
| 1 | 2.0 | 4.50 | 6.50 |

Véase Concreto común, § 22, pág. 1299.

**18.** Cada partícula de arena debe estar cubierta de cemento y cada partícula de piedra cubierta de mortero, de modo que las piedras ó los granos de arena no se toquen.

**19.** Para asegurar este resultado, hágase la mezcla con una de las máquinas más modernas, introduciendo primero la cantidad medida de agua y luego el cemento para hacer un mortero líquido que entre fácilmente en los vacíos más pequeños de la arena, y que después penetre en el menor tiempo posible. El mortero que resulta les todavía suficientemente líquido y entra en todos los vacíos de la piedra. (Wm. B. Fuller, Trans. A. S. C. E., vol. 51, pag. 135, dic. 1903.)

Para el uso de la cal, véase Experiencias, etc., 82 *a*, pág. 1392.

**20.** Para hacer planchas delgadas con un concreto de 2 partes de cemento para 5 de ceniza fina de carbón bituminoso reforzado con tejido de alambre, empleó el Sr. W. K. Hatt (Trans., A. S. C. E., vol. 51, pág. 120, dic. 1903) una solución de 5% de alumbre molido, en lugar de la mitad del agua indicada, y una solución de 7% de jabón, en lugar de la otra mitad. Esto fortaleció y endureció el concreto de cenizas en un 50%, y disminuyó su absorción en 50%. La sola **solución de jabón** disminuyó la absorción, pero no fortaleció el concreto. El mortero de arena no se fortaleció mucho por el tratamiento de jabón y alumbre, pero su absorción se disminuyó un 50%.

**21.** Si no se pueden evitar las juntas, pueden mojarse primero y luego cubrirse con pasta de cemento puro ó mortero de cemento 1 : 1 sobre el cual se coloca la nueva obra antes que se endurezca la pega.

**22.** La permeabilidad de los revestimientos de concreto de los acueductos, etc., puede disminuirse abriendo agujeros al través de ellos y metiendo á la fuerza mortero líquido detrás por medio de bombas adecuadas. El mortero líquido aparece á veces en muchos puntos, indicando que pasa no sólo por las grietas, sino también por la masa del concreto. Este método fué usado con éxito en el acueducto de agua filtrada de Torresdale, Filadelfia.

**23. Superficial.** Para revocar el interior de un aljibe cubierto de agua clara, usó el Sr. Edwd. Cunningham 0.56 kg de jabón blando para cada 5 baldes de agua y 1.35 kg de alumbre por saco de cemento. El mortero era fácil de manejar con la cuchara, pero tenía un olor nauseabundo. Se colocaron 2 capas de no más de 12 mm. Una pared divisoria de 45 cm no presentó ninguna filtración cuando á un lado contenía 5 m de agua. El jabón estaba hecho de grasas clarificadas, y costaba 16 cts. por kg; precio muy subido. Para 1 parte de cemento y 2 partes de arena, se necesitaron de 23 á 34 lit de agua y 6 kg de alumbre para cada barril de cemento. (Trans., A. S. C. E., vol. 51, págs. 127–8, dic. 1903.)

**24.** Como tratamiento **externo**, encontró el Sr. Richd. H. Gaines, Junta de Abasto de Agua de Nueva York (Trans., A. S. C. E., vol. 59, pág. 160, dic. 1907), « bastante eficaz, pero muy costoso en obras grandes », el procedimiento Silvester de jabón y alumbre (pág. 1266).

**25.** El **asfalto** puede aplicarse con éxito á superficies secas solamente. Hácese quebradizo y pierde su eficacia al oxidarse; pero con frecuencia impedirá derrames hasta que la obra se haya hecho impermeable á las infiltraciones. Véase §11, pág. 1315.

**26.** La superficie del concreto debe estar limpia y debe dársele primero una mano delgada de asfalto líquido, diluído con bencina. Éste entra en los poros del concreto y obra como una pega. Sin esto la capa de asfalto no se adherirá al concreto.

**27.** Las capas de asfalto deben hacerse continuas y protegerse del deterioro, de su tendencia á escurrirse y del desgaste colocándolas entre capas alternadas de concreto ó cubriéndolas con enladrillado ó mampostería.

**28.** Los túneles, subterráneos y cavas debajo del nivel del agua se han hecho enteramente impermeables con capas enterizas de papel grueso de techado bien impregnado de alquitrán ó asfalto y colocado entre los muros exteriores é interiores de concreto.

**29.** Los dos depósitos del acueducto de Queen Lane (Filadelfia), originariamente revestidos con concreto de cemento sobre una capa batida de arena arcillosa y que contienen 1,447 millones de litros de agua en 9 m de profundidad, fueron revestidos otra vez con asfalto de La Bermúdez en 1896–7. Al piso se le puso 5 cm de concreto de asfalto con una capa delgada, arriba, de asfalto líquido caliente; en los declives dos capas de asfalto líquido caliente con aspillera (cañamazo) entre ellas fijándose esta coleta arriba por medio de barras horizontales de hierro ó madera, á las cuales va arrollada é introducida en el pavimento de asfalto. Mientras se llevaba á cabo esta obra, se revestía de igual manera el estanque del sur del depósito da Roxborough (555 millones de litros y de 7.5 m de profundidad). En el estanque del norte, se empleó asfalto de Alcatraz (California), los declives y los lados fueron tratados con concreto de asfalto. Todos estos cuatro estanques han estado desde entonces en constante uso, sin filtración notable.

### Módulo de elasticidad, E. Véanse §§ 12 y 13, pág. 1321.

**30.** Cuando se somete el concreto á prueba de compresión su diagrama es generalmente una curva en toda su extensión; su módulo de elasticida d

$$E = \frac{\text{esfuerzo por unidad de superficie}}{\text{acortamiento por unidad de longitud}},$$

disminuye á medida que aumenta el esfuerzo.

## Resistencia.

**31.** Siendo el concreto frágil y de **tensión** débil, generalmente, y con razón, **no se aprecia** aquélla y se cuenta principalmente con su resistencia á la compresión; su resistencia á la tensión y el esfuerzo cortante se expresan como fracciones de su compresión.

**32. La resistencia á la compresión** se determina con preferencia experimentalmente por medio de cubos. La unidad de fuerza compresiva disminuye cuando la proporción largo/lado, aumenta, y, en muestras semejantes, cuando aumentan sus dimensiones.

**33. Prismas** de concreto, probados á la compresión por sus extremos, fallan de ordinario cortándose por planos oblicuos á los ejes de los prismas. Sobre estos planos oblicuos la unidad del esfuerzo cortante es como la mitad de la fuerza de ruptura por compresión.

**34.** La resistencia varía mucho con la naturaleza del concreto.

**35.** Para **cubos** de mezclas de cemento Portland de 30 cm que tengan de 6 á 18 volúmenes de (arena+agregado) para 1 volumen de cemento, deduce el Sr. **Edwin Thacher**, de los datos del Experimento 18 *a*, la fórmula de la línea recta (modificada por el traductor para el sistema métrico),

$$S = (M - NX) \ .0703$$

en que

S = á la fuerza máx de compresión en kg por cm cuad;
X = n.º de partes de arena para 1 parte de cemento;
M y N = valores como se expresan abajo:

| Edad = | 7 días | 1 mes | 3 meses | 6 meses |
|---|---|---|---|---|
| M = | 1,800 | 3,100 | 3,820 | 4,900 |
| N = | 200 | 350 | 460 | 600 |

El Sr. Thacher cree que para mezclas prácticas « la fuerza del concreto depende principalmente de la fuerza del mortero y no, en gran parte, de la cantidad de piedra ». En estos ensayos el volumen de piedra fué siempre dos veces el volumen de arena.

**36.** Pero pocos ensayos se han hecho para determinar la **resist á la tensión** del concreto. Generalmente se considera como de un décimo á un octavo de la de compresión, y **el esfuerzo cortante** como de 1.2 á 1.3 veces la resist á la tensión.

**37.** El prof. L. J. Johnson (Jour., Assn. Eng. Socs., vol. 38, n.º 6, pág. 310, junio, 1907) probó 25 vigas de cemento armado, .075 × .27 × 2.44 m, cargadas á 15 cm de cada apoyo; 19 de las vigas eran de 1 : 2 : 2¾ de escoria volcánica escamosa; 6 de 1 : 2,5 : 5. Todas las **vigas fallaron por resbalamiento, dislocación, de la armadura interior**; las vigas de 1 : 2 : 2¾, de 137 á 143 días de construídas, resistieron con éxito esfuerzos cortantes de 16.38 á 40.28 kg por cm cuad, término medio 33; y las vigas de 1 : 2.5 : 5, 34 á 53, término medio 44.

**38. En las vigas**, debido á la elevación del eje neutro, bajo carga, la **unidad máxima de la resistencia de la fibra**, ó módulo de ruptura, es como de 1.6 × la unidad de resistencia á la tensión.

## Fragua.

**39.** La fragua es, por supuesto, una función de la **pasta de cemento**. Véase Mortero. Aquí tratamos de la fragua en lo que se relaciona con el concreto como un cuerpo compuesto.

**40. Temperatura.** En tiempo cálido el concreto fragua mucho más ligero que en el frío, y la carga puede por tanto aplicarse más pronto; pero el tiempo requerido varía con la clase de construcción y del concreto.

**41.** Carga gradual. Cuando la carga es estática ó se aumenta gradualmente, el tiempo puede ser más corto que cuando se la aplica de súbito ó está sujeta á choque.

**42.** « Como regla general, los **estribos y pilas de puentes** de concreto hecho con cemento Portland deben dejarse fraguar por lo menos un mes antes de usarse, si se han construído durante tiempo cálido ordinario. Si se han construído durante el frío, su uso debe aplazarse, si fuese posible, hasta que comience el calor. » (W. A. Rogers, R. R. Gaz, '00/julio/27, pág. 514.)

**43. Se han colocado vigas** de planchas de acero sobre estribos de concreto de cemento Portland sin que hagan daño, 2 semanas después de terminados los estribos y en tiempo cálido; pero en otra obra de la misma naturaleza, acabada á principios de diciembre, se encontró que estaba poco sólida en su interior á principios del siguiente marzo.

## Efectos del calor y del frío.

**44.** La helada casi siempre daña el mortero ó concreto de cemento **natural** á tal extremo que hay que reemplazarlo con nuevo material.

**45.** Con concreto de cemento Portland la **helada suspende la fragua** y el endurecimiento del mortero mientras esté helado el material. La aparente pérdida de resistencia, en muestras heladas, puede obedecer simplemente á dicho retardo en la fragua.

**46.** Si bien la helada rara vez influye reduciendo de modo importante el máximo de resist del concreto de cemento Portland, **puede**, sin embargo, **producir graves resultados** dándole al concreto una dureza aparente, que ocasiona una prematura retirada de las armaduras ó la aplicación de cargas indebidas, que pueden producir la falla del concreto al deshelarse, si no ha fraguado lo suficiente antes de helarse.

**47.** Si poco después que se ha helado el mortero en todo el espesor de un muro, le da el sol sobre una de sus caras, lo suficiente para ablandar el mortero de esa cara, mientras que el mortero que está detrás permanece duro, es claro que el muro está expuesto á asentarse del lado calentado y por lo menos se inclinará hacia afuera si no se cae.

**48.** Si la helada se efectúa después que el cemento ha hecho su **fragua inicial**, hay poco peligro. No debe hacerse un muro delgado á $< 28°$ F (—2.2 C) en una temperatura ascendente, ni á $< 32°$ (0° C) en una descendente.

**49.** Cuando el concreto se ha helado antes de endurecerse en las aceras y muros, es posible que se cuartee **una costra delgada** y se desprenda. El acabado que queda granoso ó hecho á cuchara se astilla á veces al helarse.

## Protección.

**50. La protección contra la helada** es costosa é incierta. Por tanto, debe evitarse, hasta donde sea posible, el trabajo de concreto en tiempo de heladas.

**51. Abrigo y calefacción de la obra acabada.** Pueden usarse tiendas ó mamparas; pero los tinglados de madera son más eficaces.

**52.** El concreto debe cubrirse, tan pronto como se coloca, con lona, sacos de cemento vacíos ó papel alquitranado, ó con una gruesa capa de arena, paja, abono, serrín ú otros malos conductores del calor. La paja debe ser $< 30$ cm de espesor. El abono es lo mejor, pero mancha la obra. La lona, etc., debe mantenerse á una ó dos pulgadas distante del concreto, dejando un espacio de aire; ó pónganse dos telas.

**53. Calefacción de los materiales.** La piedra se caldea frecuentemente amontonándola sobre un tubo ú horno improvisado y prendiendo fuego dentro de él; ó sobre un serpentín provisto de numerosos agujeros pequeños, metiéndole vapor por dentro. El concreto debe usarse antes que el vapor se condense y congele. La arena se caldea sobre una estufa larga de palastro.

**54. Hágase bajar el punto de congelación del agua de mezcla** por la adición de substancias químicas.

**55.** La sal es el material más barato y más comúnmente usado. Ella baja el punto de congelación como $\frac{3}{4}°$ C por cada 1% de sal agregado al agua. Una solución de 10% (6 kg de sal por barril de cemento) baja el punto de congelación como 8° C y no daña la fuerza del concreto. Para 0° C disuélvase .45 kg de sal en 68 lit de agua; agréguense 3 onzas de sal por cada 3° bajo 0° C. (Jefe de Ingenieros, E. U. de A. Informe, 1895.) Mayores proporciones de sal parecen debilitar el concreto.

**56.** El cloruro de calcio en solución de 15%, baja el punto de congelación unos 11° C y no debilita el mortero. Absorbe rápidamente la humedad y es posible que, si se muele seco con la escoria del cemento Portland, aun hasta la cantidad de 0.5%, haría que el material absorbiese humedad. El cloruro se disuelve con extrema rapidez y puede agregarse al agua de la mezcla. (Prof. R. C. Carpenter, Cornell Univ., Sibley Jour. of Eng., jen 1905.)

**57.** La mayor parte de un montón de arena ó piedra puede estar en condición de usarse, aunque la superficie esté helada.

**58.** En invierno podemos **reducir las áreas** de las capas expuestas de la obra, colocando los tabiques divisorios interiores de las secciones del muro en construcción más cerca unas de otras. Un día de trabajo la llevará entonces á mayor altura y requerirá el uso de armaduras más fuertes.

**59.** Los morteros, colocados al aire libre, sufren más ó menos, **secándose** en vez de **fraguar**, cuando la temperatura excede de 18° á 23° C; pero si se mezclan sólo en pequeñas cantidades á la vez y se colocan pronto en la mampostería, de

piedra húmeda, de modo que estén abrigados del aire, el daño se reduce mucho. La arena y la piedra deben estar **húmedas**, no mojadas, en tiempo de calor, y puede usarse **un poco** más de agua en la pasta de cemento; también, si fuese posible, no sólo el mortero, mientras se mezcla, sino también la mampostería debe ponerse á la sombra.

## Expansión.

**60.** En los climas variables, los **cilindros de hierro colado llenos de concreto** son frecuentemente hendidos horizontalmente por expansiones y contracciones desiguales. En tales construcciones lo más seguro es considerar los cilindros como simples moldes del concreto y contar tan sólo con éste para soportar la carga.

**Para coeficientes de expansión**, véase Cemento armado, § 9, pág. 1321.

**61. Cuarteaduras y juntas.** En estribos ó alcantarillas de más de 18 m de largo, divídase el muro en secciones de unos 12 m y conclúyase una sección antes de empezar la otra. La contracción hará abrir la junta y así se evitarán grietas al través del cuerpo del muro. Pueden completarse sin parar, secciones cortas y evitarse así juntas horizontales. « Las pequeñas grietas, que sería difícil encontrar en una mampostería de piedra, se ven muy claramente en el concreto. » (W. A. Rogers, R. R. Gaz, '00/julio 6, pág. 461.)

**62. Efecto de altas temperaturas.** Durante la calcinación de los materiales para el cemento Portland, se expulsa el agua químicamente combinada. Cuando, en las mezclas, se devuelve esta agua al material, se efectúa el endurecimiento; pero al volver á aplicar temperaturas, suficientemente altas para expulsar otra vez el agua, invierte el proceso de endurecimiento y disgrega el material.

## Efectos químicos.

**63.** « La pérdida del agua de cristalización del concreto empieza probablemente á unos 260° C y se completa á unos 480° C; pero esto enfría las masas circundantes y aumenta así la resistencia del concreto al calor. » J. C.

**64. Rehidratación.** Probetas tenidas de 6 á 8 horas á la temperatura de 536° á 643° C (no en contacto con la llama) dejándolas enfriar, no presentaron prácticamente ninguna fuerza, pero una inmersión de 28 días en agua les devolvió la misma fuerza que tenían las probetas no calentadas.

**65. Resistencia al fuego.** En arena de cuarzo el coeficiente de expansión es dos veces el del feldespato, y la expansión en una dirección es el doble de la expansión en dirección perpendicular á ella.

**66.** En el incendio de Baltimore el daño producido al concreto expuesto á las llamas rara vez llegó á una profundidad mayor de 12 mm, aunque los ángulos salientes fueron en algunos lugares redondeados por las llamas con un radio de unos 5 cm.

**67. El agua de mar** aparentemente no afecta el concreto cuyas proporciones asegure una densidad máxima y que esté perfectamente mezclado. El daño ocasionado por el agua de mar que se dice tiene lugar á nivel del agua se debe probablemente, en gran parte, á las heladas. J. C.*

**68.** La acción destructora de la **electrolisis** sobre el concreto se debe aparentemente á condiciones anormales que rara vez ocurren en la práctica. J. C.

**69.** Los **ácidos** dañan el concreto fresco; al de primera calidad perfectamente endurecido, lo afectan sólo de modo apreciable los ácidos fuertes, que también dañan seriamente á otros materiales. J. C.

**70.** En la utilización de terrenos áridos, donde el suelo está muy cargado de **sales alcalinas**, sufren el concreto, la piedra, el ladrillo, el hierro y otros materiales bajo ciertas condiciones. Esta acción puede impedirse con el uso de una capa aisladora. J. C.

**71.** El concreto bien hecho y que tenga una superficie cuidadosamente acabada y endurecida, resiste á la acción del petróleo y de los **aceites** de máquina ordinarios. Los aceites que contienen ácidos grasos parece que lo dañan. J. C.

**72.** Los **gases** de ácido sulfuroso y de ácido sulfúrico, combinados con la humedad, corroen el concreto, especialmente si se calienta.

---

* J. C. Informe de la Comisión Común, A. S. C. E., A. S. T. M., Am. Ry. Eng. y M. W. Assn., y Assn of Am Cem. Mfrs., enero '09.

### Pruebas del concreto en la obra.

**73. Las pruebas de concreto en la obra** pueden hacerse por análisis de una masa del interior del concreto, obtenido con un **taladro de penetración** *. Los huecos del taladro se llenan luego con mortero líquido**.

**74. La proporción del cemento y la arena**, en el mortero, se encuentra por medio de las cantidades que quedan sin disolver en ácido hidroclórico. Así se prueban separadamente la arena y el cemento, de las clases empleadas, y el mortero, tomado del interior. (Prof. R. L. Wales, en E. N., '08/enero 9, pág. 46.)

**75. La proporción del mortero y la piedra**, en el concreto, se encuentra (1) por separación efectiva, pesando la piedra y el mortero por separado ó (2) averiguando separadamente, y comparando los pesos específicos de la piedra el mortero y el concreto.

## CEMENTO ARMADO

**1.** La resistencia á la tensión y al esfuerzo cortante del concreto son bajas en comparación con su resistencia á la compresión. Por esto incrústanse varillas ó barras perfiladas en las estructuras de concreto, en aquellas partes sujetas á tensión y á esfuerzos cortantes, y en posiciones tales que soporten dichos esfuerzos.

**2. Usos.** La armadura ó armazón se usa principalmente en las partes de vigas y tirantes (inclusive losas de piso), columnas, muros, muros de sostenimiento, represas, etc., que soportan tensión; pero es también útil en muchos otros casos, como para impedir grietas en las superficies, para lo cual se coloca á pocos centímetros detrás de la cara un ligero tejido de metal (malla de alambre, metal desplegado, etc.); para impedir fracturas causadas por cambios súbitos inevitables en la secciones transversales, para unir muros que se encuentran en un ángulo y susceptibles de separarse uno de otro al asentarse; en alcantarillas para que puedan resistir la tensión horizontal debida á la presión del terraplén. Para este fin pueden usarse cadenas viejas, ó barras livianas, con pernos introducidos por huecos, para aumentar la adhesión.

**3. Seguridad.** Los edificios modernos de cemento armado son prácticamente monolíticos y por lo tanto más rígidos que las construcciones de armazón de acero.

**4.** En cambio, en un edificio de acero los pormenores son ejecutados con más exactitud y la obra es generalmente erigida por hombres hábiles á menudo empleados de los fabricantes de acero; de suerte que hay poca probabilidad de dañar el material en construcción, mientras que en obras de cemento armado, el mejor material puede dañarse al usarlo y hacer así insegura la obra.

**5.** Un buen concreto protege el acero incrustado de la **corrosión**, tanto sobre como bajo el nivel del agua dulce ó del mar; pero el agua puede penetrar el concreto poroso y oxidar el metal. El concreto colocado muy seco puede hacerse poroso.

**6.** El acero empleado en el hormigón armado tiene generalmente su máx de resistencia entre 3,500 y 4,900 kg por cm cuad, y su límite de elasticidad entre 1,750 y 2,450 kg por cm cuadrado; pero trabajado en frío puede elevar su límite de elasticidad á 2,800 ó 3,500. Para economizar acero se hacen barras llamadas « deformadas », de acero laminado, con un límite de elasticidad mucho más alto (se le calculan 3,500 á 4,550 kg por cm cuadrado); pero véase Armaduras de barras, págs. 1180, etc. Como en el hierro y el acero laminados en general, el módulo elástico puede suponerse que es por término medio de 2,100,000 kg por cm cuadrado. Véase § 11.

**7. Concreto.** En general, la necesidad de trabajar el concreto alrededor de las barras de la armadura exige que el agregado para el concreto en obras de cem armado sea menor de lo que sería permitido en obras ordinarias, y la importancia vital de la adhesión exige que todos los materiales para el concreto sean de los mejores y el mortero ni muy líquido ni muy seco.

### Expansión, contracción, etc.

**8.** La **contracción** del concreto, mientras fragua al aire, produce compresión en la armadura y tensión en el mismo concreto. Cuando fragua bajo el agua, la expansión del concreto produce los efectos contrarios.

---

* Hecho por la Cyclone Drill Co., Orrville, O., inclusive taladros pequeños movidos á mano.

** B. G. Cope, en E. N., '08/enero/9, pág. 41.

**9.** El **coeficiente de expansión** lineal, *a*, de un material, es aquella fracción de su longitud original que una barra de dicho material gana ó pierde por cada cambio de 1° en su temperatura.

Aproximadamente :

| | | Para 1° centígrado. |
|---|---|---|
| En acero..... | 10,000 *a* = | .117 |
| En concreto..... | 10,000 *a* = | .108 |

**10.** El gran número de construcciones de cemento armado que han estado expuestas por muchos años á cambios extremos de temperatura, sin sufrir por diferencias de expansión, confirma los resultados de las experiencias arriba citadas, estableciendo que la diferencia entre los coeficientes de expansión de los dos materiales es despreciable.

## Módulo de elasticidad.

**11.** El **módulo de elasticidad, $E_s$, del hierro y del acero laminados,** de todas clases (pág. 482 *b*), es notablemente uniforme y constante, variando ordinariamente entre 1.9 á 2.2 (término medio, digamos 2.1) millones de kg por cm cuad.

**12.** Por el contrario, el **módulo de elasticidad, $E_c$, del concreto** varía mucho no sólo entre diferentes mezclas diversamente manipuladas, y entre diferentes muestras hechas bajo condiciones semejantes de materiales semejantes, sino en la misma muestra bajo diferentes intensidades de carga, de modo que al exponer los resultados de los experimentos se acostumbra especificar el campo de la variación de la unidad de resistencia á cuyo alrededor se hicieron las observaciones.

**13.** En el **concreto de piedras,** $E_c$, varía de 1.5 á 4 (término medio, digamos 3) millones de lbs por pulgada cuadrada = .1 á .28 (término medio, digamos .21 millones de kg por cm cuad. Véase Experimento 81 *a*, pág. 1387 En concreto de ceniza gruesa, $E_c$ es ordinariamente de 20 á 50 0/0 menos que en concreto de piedras. Véase § 30, pág. 1316.

**14. La relación,** $n$ (á veces llamada $r$ y $R$) $= E_s/E_c$, entre los módulos de elasticidad del acero y del concreto respectivamente, se supone generalmente entre 10 y 15 para concreto de piedras, con valores más altos para el concreto de ceniza gruesa. Véase Especificaciones, § 107, pág. 1414. Debido á la variabilidad de $E_c$ (véase § 12), no puede ser una cantidad constante, aun dentro de un solo experimento llevado de una carga cero á la carga de ruptura.

**15.** La relación, $n$, es, sin embargo, de uso constante é **importante** en todos los cálculos relativos á la conducta mutua del concreto y del acero.

**16.** Los experimentos de Considère (Experimento 16 *a*, pág. 1357, parecieron demostrar que el concreto cuando, está armado (obligado, por su adhesión al acero, á participar de sus movimientos) efectivamente sufría, sin fractura, **estiramientos** mucho mayores que cuando no estaba armado; pero experimentos posteriores (36, 38, 81 *e*, 81 *f*), observando la superficie del concreto más detenidamente, han indicado que el supuesto estiramiento del concreto se debía en realidad á la formación de grietas que antes habían escapado á la observación. Si la adhesión entre el concreto y el acero es uniforme, el agrietamiento debe estar igualmente distribuído sobre el área de contacto, y las grietas deben, en consecuencia, ser muy numerosas y muy delgadas, probablemente tan delgadas que no lleguen á poner en riesgo los materiales por la filtración del agua.

## Adhesión. Véase § 58, pág. 1337.

**17.** Con **mezclas ricas y húmedas,** tales como se usan en el cemento armado, el cemento se adhiere muy íntimamente al acero.

**18.** Después que ha sido vencida la adhesión propiamente dicha, la **remoción** de las piezas de acero del concreto encuentran todavía el obstáculo de la **fricción** entre los dos.

**19.** De esta resistencia de la adhesión y fricción á las fuerzas que tienden á vencerlas, depende, por supuesto, la seguridad de la construcción.

**20.** Tanto á la adhesión como á la fricción, y en particular esta última, las afecta considerablemente la naturaleza del concreto y su conducta bajo los esfuerzos y cambios de temperatura.

**21.** En las **pruebas** directas **para la adhesión** ya se ejerza tensión ó compresión en el acero, el concreto se halla siempre bajo compresión, que le produce alguna expansión lateral, y por tanto la presión aumenta sobre la armadura interior. En consecuencia, la adhesión puede encontrarse más alta (en igualdad de circunstancias) que en las vigas, donde no existe esta condición.

**22.** Por otra parte, cuando las barras horizontales de la armazón, en una viga, se doblan hacia arriba, cerca de los extremos, y pasan á la región de compresión y (como sucede á menudo) llegan á un punto por encima del apoyo, las altas presiones sobre la barra, en esas porciones, pueden darle mayor adhesión de la que podría tener una barra recta bajo prueba directa.

**23. Con grandes longitudes de empotramiento**, la tensión, en el acero, bajo grandes fuerzas, puede ser tal, que contraiga lateralmente el acero, lo bastante para reducir la adhesión. En consecuencia, las pruebas donde el acero se **empuja** en el concreto presentan adhesiones más altas.

**24. Adhesión máxima.** En general, los ensayos (véase Experiencias y práctica 64 *a*, *b*) dan, como máxima adhesión de un buen concreto á las barras redondas y lisas, de 14 á 21 kg por cm cuadrado en la superficie de contacto. Con barras redondas y lisas, en una viga, obtuvo Kleinlogel (Beton und Eisen, 1904, págs. 227 y sig.) 39 kg por cm cuadrado. Los resultados en la práctica difieren mucho, por lo general, de los que se obtienen en el laboratorio.

**25. Carga de trabajo de las uniones.** En vigas sujetas á choques, se conceden 3.5 kg por cm cuadrado: para carga quieta se concede á veces el doble de esto. Véase Especificaciones, §§ 113-115.

## COLUMNAS DE CEMENTO ARMADO

**1.** Una columna de concreto tiene de ordinario barras longitudinales de acero incrustadas cerca de la superficie en toda su extensión. Si no hay flexión ni resbalamiento entre el concreto y el acero, los dos materiales deben acortarse igualmente bajo la carga. En consecuencia (pág. 480, Ec /3), si L=longitud original, $l$=aumento ó disminución de la longitud, $a_s$ y $a_c$=áreas de secciones transversales; $s_s$ y $s_c$=esfuerzo por unidad de superficie, $E_s$ y $E_c$=módulos de elasticidad, del acero y del concreto, respectivamente, tenemos

$$s_c = E_s\, l/L; \quad s_c = E_c\, l/L; \ldots\ldots (1)$$

y como $l/L$ es necesariamente el mismo para ambos materiales,

$$s_s/s_c = E_s/E_c = n; \quad s_s = s_c\, n; \ldots\ldots (2)$$

y el esfuerzo total en el acero $= a_s\, s_s = a_s\, s_c\, n \ldots\ldots (3)$

— — en el concreto $= a_c\, s_c \ldots\ldots (4)$

— — en la columna $= P = a_s\, s_c + a_c\, s_c = s_c\,(a_c + a_s\, n) \ldots\ldots (5)$

$$a_c = P/s_c - a_s\, n. \ldots\ldots (6)$$

$$s_c = P/(a_c + a_s\, n) \ldots\ldots (7)$$

**2. Ejemplo.** Si una columna cuadrada de concreto de 40×40 cm y 3.60 m de largo tiene incrustada en cada esquina una barra redonda de acero de 2.5 cm de diámetro, tendremos que el área de la sección transversal de cada barra será=4.90 cm cuad; y la fuerza de compresión permitida, $s_c$, por unidad de superficie sobre el concreto=35 kg por cm cuadrado. Para saber el peso que puede soportar la columna, tenemos :

Area; $a_c$, del acero=4×4.906=19.624 cm cuad;
Area, $a_c$, de concreto=40×40 — 19.62=1,580.38 cm cuad;
$E_s$=2,100,000 kg por cm cuad;
$E_c$= 175,000 kg por cm cuad;
$n = E_s/E_c = 12$;

| | | |
|---|---|---|
| Carga total que soporta el concreto $= a_c\, s_c$ =1,580.38×35 kg=.. | | 55,312 kg |
| — — — el acero $= a_s\, s_c\, n$=19.62×35×12=..... | | 8,240 |
| — — — la columna..... | | 63,552 kg |

**3.** Aquí el acero toma 100×8,240 ÷ 63,552=12.9% de la carga total, que es una proporción segura. Esta proporción no debe exceder de 20% ó, cuando más, de 30%.

**4. Una regla que conviene** observar es la de contar cada centímetro cuadrado de acero, en columnas, como equivalente al valor de $n$ centímetros cuadrados de concreto.

**5.** Los constructores cuidadosos cargan las columnas de concreto aproximadamente como sigue :

| Largo | Mezcla. | | | |
|---|---|---|---|---|
| diám | 1:1.5:3 | 1:2:4 | 1:2.5:5 | 1:3:6 |
| | $p=P/a$=Carga en kg por cm cuad. | | | |
| <12..... | 42 | 35 | 24.5 | 24.5 |
| 12 á 18..... | 38.5 | 31.5 | 21 | 21 |

**6. En general se colocan** simétricamente **barras** longitudinales de refuerzo cerca de la superficie del concreto y se cubren con 4 á 5 cm de concreto. Las barras deben estar atadas unas á otras por varillas más delgadas ó por alambres, á intervalos que no excedan del diámetro de la columna.

**7.** Las especificaciones exigen de ordinario que el área en conjunto de la sección transversal de las barras de compresión no exceda de 2 á 3% del área de la sección transversal de la columna.

**8.** En edificios de tres ó cuatro pisos, las barras de cada sección se doblan hacia adentro, cerca de sus extremos, para formar un cilindro de 45 ó 50 cm de alto, de diámetro más pequeño que el cilindro principal de abajo, y la sección inmediata de arriba se ajusta sobre esta porción de modo que las dos secciones recubran la parte reducida.

**9.** Debido á sus áreas de sección transversal, mucho mayores, y á las más bajas unidades de resistencia en sus materiales, las columnas de cemento armado están menos expuestas á flexarse que las columnas de acero.

**10. Para cargas máximas sobre columnas de cemento armado longitudinalmente y sujetas á flexión,** tenemos la fórmula de Rankine :

$$p = \frac{P}{a} = \frac{s}{1 + mK^2} \qquad (8)$$

en que

$P$=carga máxima total sobre la columna;
$a$=área de la sección transversal de la columna;
$p=P/a$=carga máx por unidad de superficie;
$s$=resist máxima de compresión por unidad de sup en los cubos de concreto;
$K=L/r$=longitud /radio mínimo de giro.

El profesor Morsch hace $m=.0001$. Eisenbetonbau, '08, pág. 73.

## Columnas con sunchos.

**11.** Las columnas reforzadas con sunchos (ó espirales) de acero, ó con alma encorvada en forma cilíndrica, presentan grandes máx de resistencia y se usan profusamente; pero sufren considerables deformaciones antes de que se desarrolle la resistencia de los sunchos, pues éstos obran de modo semejante á un cilindro de acero, lleno de arena, que no puede desarrollar su fuerza hasta que la arena no está comprimida.

**12.** Los experimentos en Watertown (Ensayo de metales, 1905) demostraron que, cuando la columna está sujeta á cargas de 7 á 70 kg por cm cuadrado, la unidad de deformación lateral es menos de la cuarta parte de la unidad de deformación longitudinal. Así, si la columna se acortaba .004 de su largo, su diámetro aumentaba menos de .0001 de su dimensión original.

**13.** De pruebas hechas en la Universidad de Illinois (Am. Soc. Testg Matls., Procs., 1907, pág. 382) deriva el prof. A. N. Talbot las siguientes **fórmulas** para las resistencias máx de las columnas cilíndricas de concreto sunchadas 1 : 2 : 4 : de mezcla húmeda de 60 días; término medio; columnas de 30 cm de diámetro y 3.05 m de largo. Cubierta, sobre los sunchos generalmente 6 mm. Sunchos, 25 mm de ancho, tipos n.os 8, 12, 16, soldados eléctricamente y separados generalmente 5 cm de centro á centro. Sean

$p$=resistencia máx de la columna, kg por cm cuad;
$c$=proporción entre los aros y el alma del concreto;
112=resist á la compresión del concreto, kg por cm cuad.

Entonces,

Para acero dulce $p=112+4{,}550\ c$;..... (9)
— — mejor $p=112+7{,}000\ c$..... (10)

**14.** Suponiendo que la resistencia máx por unidad de superficie, en la armazón longitudinal de la columna, es 25 veces la del concreto, los sunchos produjeron un máx de fuerza adicional de 2 á 4 veces la producida por la armazón longitudinal.

**15.** Los Ensayos del Sr. Considère (« Génie Civil », nov. 1902), con columnas de concreto con armazones espirales, indican que las barras que forman los sunchos deben tener un diámetro aproximado de $^1/_{40}$ del diámetro de la columna; que el paso de las espiras (distancia entre los sunchos) debe ser de $^1/_5$ á $^1/_6$ del diámetro de la columna, y que el acero, en los aros ó espirales, agrega, á la última resistencia de la columna, 2.4 veces tanto como el mismo peso del metal empleado como armazón longitudinal. Da la fórmula :

$$\text{Máximo de la carga total en la columna} = 1.5\, a_c c + s_c (a + 2.4\, A) \ldots\ldots \quad (11)$$

en que

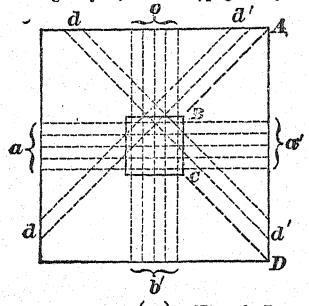
$a_c$ = área de la sección transversal de la columna dentro de la espiral;
$c$ = máxima resistencia á la comp por unidad de sup de concreto ordinario en bloques cortos;
$s_c$ = límite de elasticidad del acero;
$a$ = área de la sección transversal del refuerzo longitudinal existente;
$A$ = — — — — del refuerzo longitudinal de igual peso que la espiral.

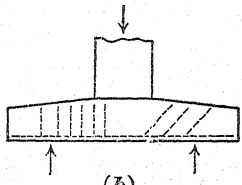
$1.5\, a_c$ se toma como representando el área de toda la sección transversal del concreto.

## Bases de columnas.

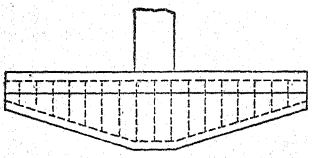
**16.** En las **bases de columnas** los esfuerzos son análogos á los de una plancha ó baldosa de piso que descansa sobre una columna; pero, debido á lo relativamente estrecho de la base, los momentos y esfuerzos cortantes son fuertes y requieren considerable profundidad. Los mayores esfuerzos obran debajo de los bordes de la columna. Las barras horizontales, en la base, son análogas á las barras cerca del tope de una viga sobre el soporte; esto es : sufren momentos negativos y algunas de ellas deben doblarse hacia arriba, ó estar provistas de estribos, precisamente fuera de los bordes de la columna.

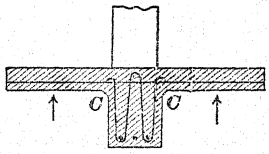
**17.** Figs. 1 y 2 (T. and M., págs. 261, 262). Fig. 1 : Dos series de barras de refuerzo principales, $aa'$, $bb'$, que se cruzan en ángulos rectos debajo de la columna, con barras diagonales, $dd'$, $dd'$. Fig. 2: Viga y baldosa combinadas. Las alas laterales de la baldosa tienden á doblarse hacia arriba, separándose de la viga en C y C.





(a) **Fig. 1.** Base de columna. (b)





(a) **Fig. 2.** Base de columna. (b)

En estas págs el autor usa la *sub s* y la *sub c* para distinguir respectivamente los coeficientes de una misma especie, en el acero ó el hierro, de los correspondientes en el concreto; así, por ejemplo, $E_c$ y $E_s$ son respectivamente los coeficientes de elasticidad en el concreto y en el acero. Lo mismo para los momentos, etc. Llamamos la atención del lector porque á veces la letrica *s* ó *c* aparece, por su pequeñez, un poco borrada.

## VIGAS DE CONCRETO ARMADO

**1.** La resistencia á la compresión del conc es de 8 á 10 veces su resistencia á la tensión. En consecuencia, en una viga de concreto armado de sección rectangular sometida á esfuerzos de flexión, ocurre la falla donde el esfuerzo obra como tensión.

**2.** La facilidad con que puede incrustarse el acero en el concreto, la igualdad práctica de los coeficientes de expansión de las dos substancias, la fuerte adhesión entre el concreto y el acero, y la facilidad de extender esta adhesión por prolongaciones ó proyecciones laterales, de la superficie del acero, facilitan combinaciones en que el principal servicio del concreto es resistir la compresión mientras que la del acero es resistir á la tensión.

**3.** El método de manufactura del concreto es tal, que su conducta, en un caso dado, es menos segura que la del acero.

Debido á esto y á la incertidumbre, en cuanto al grado de adhesión entre el concreto y el acero, de la que depende su acción combinada, la teoría de tales vigas es desde luego más complicada y menos exacta que la de las vigas de acero de secciones económicas. En el diseño de vigas de concreto armado debe hacerse la debida concesión por este respecto y todo cálculo de exagerada precisión está fuera de lugar.

### Teoría general.

**4.** Viga simple de concreto armado de sección rectangular, fig. 1.

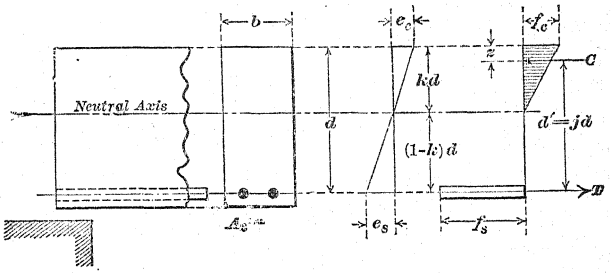


**Fig. 1.** Viga de concreto armado. Teoría.

### Hipótesis fundamentales.

1. Las secciones transversales planas antes de la flexión, permanecen planas bajo la flexión.

2. Las resistencias iniciales (por contracción, etc.) se desprecian.

3. No ocurren deslizamientos entre el concreto y el acero. Por tanto se deforman por igual.

4. La resistencia del concreto á la tensión se desprecia.

5. Los módulos de elasticidad $E_s$ y $E_c$, del acero y del concreto respectivamente, y en consecuencia su relación $n = E_s/E_c$, permanecen constantes.

**5. Observaciones** referentes á la figura 1, sean:

$b$ = ancho (perpendicular al papel) de la sección transversal de la viga;
$d$ = distancia, del lado de la viga en que se ejerce la compresión, al centro de gravedad del acero;
$kd$ = distancia del lado de la viga en que se ejerce la compresión al eje neutro;
$z$ = distancia del lado de la viga en que se ejerce la compresión á la resultante de las fuerzas de comp;
$(1-k)\,d$ = distancia del centro del acero al eje neutro;
$d' = jd$ = distancia del centro del acero á la resultante de las fuerzas compuestas = palanca del par resistente;
$j = d'/d$;
$E_s$ = módulo de elasticidad del acero; $E_c$ = módulo de elasticidad del concreto;

$e_s$=unidad de alargamiento del acero;
$f_s$=tensión por unidad de sup en el acero**;
$a_s$=área de la sección transversal del acero;
$e_c$=unidad de acortamiento del concreto*;
$f_c$=comp por unidad de sup en el concreto* **;
$a_c=bd$=área de la sección transversal del concreto por encima del centro del acero;
T=suma de los esfuerzos de tensión en el acero;
C=suma de los esfuerzos de compresión en el concreto;
$n=E_s/E_c$=relación entre los módulos de elasticidad del acero y del concreto;
$p=a_s/a_c$=relación entre el área del acero y la porción del área del concreto que está sobre el centro del acero †;
$M_s$=momento de resistencia, basado en el valor máximo permitido ‖ de $f_s$;
$M_c$= — — — — — de $f_c$;
M=momento de resistencia real, efectivo.
Entonces $a_s=pa_c=pbd$.

## Esfuerzos, momentos, diseño.

**6.** Las figs. 1 y 2 †† y los §§ 7 á 20 ilustran las **relaciones existentes entre los importantes factores**, $k$, $j$, $f_s$, $f_c$, $p$, $M_s$, $M_c$ y M; cuando ni $f_s$, ni $f_c$ exceden del límite de elasticidad. Cuando exceden de ese límite, véanse §§ 21, 22, pág. 1331.

**7.** En equilibrio, el **momento de flexión** de la carga (véase pág. 496) queda equilibrado por el **momento de resistencia** igual del par compuesto de las dos fuerzas horizontales iguales, T y C; pues estas fuerzas son respectivamente las resultantes de las fuerzas de tensión en el acero y de las fuerzas de compresión*** en el concreto.

**8. Los esfuerzos de tensión** $f_s$, en el acero, se suponen que están uniformemente distribuídos sobre toda su sección transversal, $a_s$; y su resultante, T, se toma en consecuencia como si obrase en el centro de gravedad del área del acero; pero las **fuerzas de compresión**, en el concreto, en cualquier sección transversal, decrecen uniformemente (véanse §§ 21 y 22) desde un máximum, $f_c$, en la superficie superior de la viga, hasta cero, en el eje neutro. Su resultante, C, se aplica, por tanto, en un punto distante $kd/3$ debajo de la parte superior de la viga, siendo $kd$ la distancia desde dicha parte sup de la viga hasta el eje neutro, y $d$ la distancia desde la misma parte sup de la viga hasta el centro de gravedad del acero.

**9. Valor de « j ». El brazo de palanca**, $d'$, **del par de resistencia** es por tanto

$$d'=jd=d-kd/3=d(1-k/3) \quad \ldots\ldots (1)$$

y tenemos

$$j=d'/d=1-k/3 \quad \ldots\ldots (2)$$

Para valores aproximados de $j$, véase § 12.

**10. Valor de « k ».** De la hipótesis 1, § 4, tenemos

$e_c/e_s=k/(1-k)$ (Véase triáng semejantes, fig. 1, que tienen por base $e$ y $e_s$. — *N. del T.*) ..... (3)

Del supuesto 5, tenemos

$$f_c=e_cE_c;\ f_s=e_sE_s \quad \ldots\ldots (4)$$

De aquí que

$$\frac{f_c}{f_s}=\frac{e_cE_c}{e_sE_s}=\frac{k}{1-k}\times\frac{E_c}{E_s}=\frac{k}{n(1-k)} \quad \ldots\ldots (4a)$$

---

* En las fibras más externas del lado de la compresión.
** $f_s$ y $f_c$ son las unidades de esfuerzos *reales*. Véase § 13, pág. 1327.
† Véanse §§ 15, 16, pág. 1327.
‖ Véase § 13, pág. 1327.
*** Debajo del eje neutro, el concreto está en *tensión*, pero su esfuerzo de tension se desprecia. Véase hipótesis 4, § 4, pág. 1325.
†† Las figs. 2 y 3 son hechas por el prof. A.W. French. A.S.C.E., Trans., vol. 56, 06, págs. 362, etc.

Para el equilibrio, C=T; pero

$$C = f_c\, bkd/2 \text{ (véase fig. 1)} = e_c\, E_c\, bkd/2 \quad \ldots\ldots (5)$$

$$y\ T = f_s\, a_s = f_s\, pbd = e_s\, E_c\, pbd \quad \ldots\ldots (6)$$

De aquí (igualando valores de C y T y despejando á $k$). (*N. del T.*)

$$k = 2p\frac{e_s E_c}{e_c E_c} = 2\,p\,n\,\frac{1-k}{k};$$

$$\text{ó } k = \sqrt{(p\,n)^2 + 2\,p\,n} - pn. \quad \ldots\ldots (7)$$

**11.** En consecuencia, la **posición del eje neutro** (dada por $k$) depende solamente de la razón, $p$, entre el área del acero y el área del concreto, y de la relación, $n$, entre la elasticidad del acero y la del concreto. Para valores aproximados de $k$, véase lo siguiente :

**12. Valores aproximados** de $j$ y $k$. Véase fig. 2.

| cuando | y | tenemos | y |
|---|---|---|---|
| $n=10$, | $p=.010$: | $j=.88$; | $k=.36$; |
| | $p=.015$: | $j=.86$; | $k=.42$; |
| $n=15$, | $p=.010$: | $j=.86$; | $k=.42$; |
| | $p=.015$: | $j=.84$; | $k=.48$. |

**13.** Cuando, como en el concreto armado, se usan conjuntamente dos materiales enteramente diferentes, sucede de ordinario que, debido á la imposibilidad de darle siempre á cada uno su área ideal de sección transversal, **el uno ó el otro** están inevitable y no económicamente sometidos á menos de su esfuerzo máximo permitido. Así, con un valor dado de $p = a_s/a_c$, si cargamos la viga hasta que ó bien $f_s$ ó $f_c$ llegue á su límite permitido, el otro, $f_c$ ó $f_s$, permanecerá generalmente por debajo de su límite permitido. Véase § 19 *f*. Sean $F_s$ y $F_c$ = respectivamente los **valores máximos permitidos de** $f_s$ y $f_c$.

**14. Momentos**. Para momentos de resistencia, basados sobre los **valores máximos permitidos**, $F_s$ y $F_c$, de $f_s$ y $f_c$ respectivamente, tenemos :

$$M_s = Td' = F_s a_s jd = F\, pjd^2 \quad \ldots\ldots (8)$$

$$M_c = Cd' = C jd = F_c\, bkdjd/2 = F_c\, kjbd^2/2 \quad \ldots\ldots (9)$$

**Para valores usuales**, podemos tomar (véase § 12) : $j = {}^7/_8$; $k = {}^3/_8$, $kj = {}^1/_3$. De aquí, **aproximadamente,**

$$M_s = 7F\, a\, d/8;$$
$$M_c = F_c\, bd^2/6.$$

Pero el **momento de resistencia real, M**, de la sección, en cualquier caso dado, no puede tener, por supuesto, sino *un valor;* y éste es el *menor* de los dos valores $M_s$ y $M_c$. Puesto que $jbd^2$ es común á los dos valores, M se determina investigando cuál es el menor entre $F_s p$ ó $F_c k/2$.

**15. Relación entre** $f_s$, $f_c$ y $p$. Puesto que C=T, ó $f_c bkd/2 = f_s pbd$, tenemos

$$\mathbf{f_s = \frac{kf_c}{2p}};\quad \mathbf{f_c = \frac{2pf_s}{k}};\quad \mathbf{p = \frac{kf_c}{2f_s}} \quad \ldots\ldots (10)$$

De la Ecuac (4 *a*) tenemos :

$$\frac{f_c}{f_s} = \frac{k}{n-nk}.$$

De aquí $k = \dfrac{nf_c}{nf_c + f_s}$;

$$y\ \mathbf{p} = kf_c/2f_s = \frac{.5}{\frac{f_s}{f_c}\left(\frac{nf_c+f_s}{nf_c}\right)} = \frac{.5}{\frac{f_s}{f_c}\left(\frac{f_s}{nf_c}+1\right)} \quad \ldots\ldots (11)$$

**Generalmente, p varía** de .010 á .015. Raras veces $< .005$ ó $> .020$.

**16.** Nótese que $f_s$, $f_c$ y $p$ no pueden escogerse arbitrariamente. Dados dos cualesquiera de ellos, el tercero depende de los dos así dados.

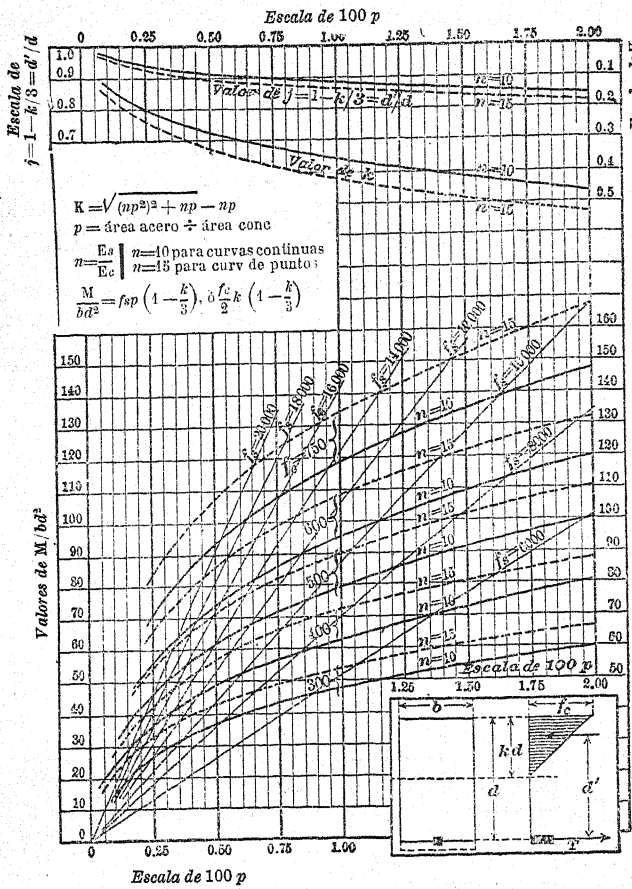

**Fig. 2.** Para esfuerzos de trabajo. (Para los máx ó de ruptura, véase fig. 3

$\mathbf{k} = \sqrt{(p\,n)^2 + 2\,p\,n} - pn$, $\mathbf{j} = d'/d$;

$\mathbf{f_s}$ = esfuerzo por unidad de superficie en el acero, $\mathbf{f_c}$ = esf por unidad de sup en el concreto en la parte sup de la viga;

$\mathbf{p} = a_s/a_c$; = proporción entre el área del acero y el área del concreto;

$\mathbf{M_s}$, $\mathbf{M_c}$ = momento de resistencia, basado sobre el valor permitido de $f_s$, $f_c$, respectivamente;

**M** = momento de resistencia, real.

$$\frac{\mathbf{M}}{bd^2} = f_s p\,(1 - \frac{k}{3}) \quad \text{ó} \quad \frac{f_c}{2}\,k\,(1 - \frac{k}{3}).$$

$n=E_s/E_c$. Las **curvas continuas** representan $n=10$; las **curvas de puntos**, $n=15$.

Las **líneas de acero** trazadas para $n=10$; aproximadamente para $n=15$.

**17. Valor de M/bd².** Sean $F_s$ y $F_c$ los valores *máximos permitidos* de las unidades de fuerzas, $f_s$ y $f_c$, en el acero y en el concreto respectivamente. Entonces, de las ecuaciones (8) y (9), § 14, tenemos (fig. 2, parte inferior):

$$M_s/bd^2=F_s pj=F_s p\ (1-k/3);$$
(líneas casi rectas para el acero)..... (12)

$$M_c/bd^2=F_c kj/2=F_c k\ (1-k/3)/2;$$
(líneas curvas para el concreto)..... (13)

Las líneas curvas de puntos y sólidas para el concreto representan $n=15$ y $n=10$, respectivamente. Las líneas casi rectas para el acero están proyectadas para $n=10$, pero son bastante aproximadas también para $n=15$.

**18.** La porción superior de la **fig. 2** da **valores de**

$$k=\sqrt{2pn+(pn)^2}-pn;$$

véase § 10) y de

$$j=1-k/3=d'/d,$$

correspondientes á valores dados de $p$, para $n=10$ y $n=15$. Nótese que $j$ varía muy poco con las variaciones de $p$.

## Ejemplos.

### I. Investigaciones.

### Se piden los momentos de resistencia $M_s$, $M_c$ y M.

(*Obs. del T.* — Para hacer uso de los, por su claridad, sencillez y utilidad práctica, admirables diagramas de las **figs. 2** y **3**, debemos convertir los datos que tengamos en metros y kg á unidades inglesas, usar el diagrama y luego convertir el resultado obtenido en medida inglesa al sistema métrico. En esta materia es facilísimo, pues nunca hay más de tres datos que convertir. Vamos á hacerlo así, en todos los ejemplos que trae el autor, para que el lector aprecie la sencillez de la operación; advirtiendo que, cuando la extremada exactitud en la conversión no sea de trascendencia en los resultados, haremos aquéllas simplemente aproximadas; convirtiendo la pulgada, por ejemplo, en 2.5 cm, cuando la verdad es 2.54, etc.)

**19 a. Dada una viga rectangular de concreto** armado de $b=20$ cm; $d=50$ cm convertidos en pulgs dan: $b=8''$; $d=20''$; $a_c=bd=8\times20=160$ pulgs cuads *; $n=E_s/E_c=15$. Sean $F_s=1{,}120$ kg por cm cuad$=16{,}000$ libs por pulg cuad, y $F_c=35$ kg por cm cuad$=500$ lbs por pulg cuad los valores *máximos permitidos* de las unidades de fuerzas, $f_s$ y $f_c$, en el acero y en el concreto respectivamente; y sea P el valor de $p$ basado sobre estas fuerzas máximas permitidas.

Entonces $F_s/F_c=32$; $\dfrac{F_s}{nF_c}+1=3.133$; y, de la ecuación (11), § 15, tenemos:

$$P=\frac{.5}{32\times3.133}=.004987,$$

como lo da la intersección, en la fig. 2, de la línea radial, para $f_s=16{,}000$ (1,120 kg por cm cuad) con la curva de puntos para $f_c=500$ (35 kg por cm cuad).

---

* *N. del T.* — Para convertir pulgs en cm se multiplican las pulgs $\times$ 2.54; para convertir cm en pulgs se multip los cm por .3937. Las libras por pulgs cuad multiplicadas por .0703 dan kg por cm cuad. Los kg por cm cuad multiplicados por 14.2234 dan lbs por pulg cuad.

**19 b. (Caso 1) Reforzado con dos barras redondas** de 19 mm=3/4"=.75 diám.

$a_s = 2 \times \pi \times 0{,}375^2 = .884$ pulgs cuad;
$p = a_s / a_c = .884 / 160 = .005525 > P$;
$pn = 15 \times .0055 = .0825$;

$$k = \sqrt{(pn)^2 + 2pn} - pn$$
$$= \sqrt{.0825^2 + .1650} - .0825 = .3322;$$
$d' = dj = d\ (1 - k/3) = 20\ (1 - .1107) = 20 \times .89 = 17.8$ pulgs:
$C = F_c\, bkd/2 = 500 \times 8 \times .3322 \times 10 = 13{,}288$ lbs $= 6{,}027.33$ kg *;
$M_c = Cd'$ (fig. 1) $= 13{,}288 \times 17.8 = 236{,}526$ lbs-pulgs $= 2{,}720$ kg-metros **;
$T = F_s a_s = 16{,}000 \times .884 = 14{,}144$ lbs $= 6{,}407$ kg *;
$M_s = Td'$ (fig. 1) $= 14{,}144 \times 17.8 = 251{,}763$ lbs-pulg $= 2{,}900$ kg-metros **;
$M = M_c =$ 236,526 — $= 2{,}720$ kg-metros.

Nótese que cuando, como en este caso y en el caso 2, $P < p$, el momento, $M_c$, basado en la fuerza máxima permitida, $F_c$ en el *concreto*, es el momento real, M. Cuando $P > p$, $M_s$ es el momento real.

**19 c. Por la fig. 2.** La intersección de la línea vertical, sobre 100 $p = .55$, con la línea radial para $f_s = 16{,}000$ lbs por pulgada cuadrada, da $M_s / bd^2 = 78.7$; y $M_s = 78.7\ bd^2 = 78.7 \times 8 \times 20^2 = 251{,}840$ lbs-pulgs; pero la intersección de la línea vertical sobre 100 $p = .55$, con curva de puntos ($n = 15$) para $f_c = 500$ lbs por pulgada cuadrada, da $M_c / bd^2 = 74$; y $M = M_c = 74\ bd^2 = 74 \times 8 \times 20^2 = 236{,}800$ lbs-pulgs.

**19 d. (Caso 2) Reforzado con 3 barras redondas**, de 2.5 cm diám=1 diám;

$a_s = 3\pi\ 0.5^2 = 2.356$ pulgs cuad;
$p = a_s / a_c = 2.356 / 160 = .01473 > P$;
$pn = 15 \times .01473 = .2209$;

$$k = \sqrt{(pn)^2 + 2pn} - pn$$
$$= \sqrt{.22^2 + .44} - .22 = .48;$$
$d' = dj = d\ (1 - k/3) = 20\ (1 - .16) = 20 \times .84 = 16.8$;
$C = F_c\ bkd/2 = 500 \times 8 \times .48 \times 10 = 19{,}200$ lbs;
$M_c = Cd' = 19{,}200 \times 16.8 = 322{,}560$ lbs-pulgs $= 3{,}716$ kg-m **;
$T = F_s a_s = 16{,}000 \times 2.356 = 37{,}696$ lbs $= 17{,}098.9$ kg;
$M_s = Td' = 37{,}696 \times 16.8 = 633{,}293$ pulgs-lbs $= 7{,}295$ kg-m;
$M = M_c =$ 322,560 — $= 3{,}716$ kg-m.

**19 e. Por la fig. 2.** La intersección de la línea vertical sobre 100 $p = 1.473$, con la línea radial para $f_s = 16{,}000$ lbs por pulg cuadrada, daría (sobre un diagrama bastante exacto) $M_s / bd^2 = 198$; y $M_s = 198\ bd^2 = 198 \times 8 \times 20^2 = 633{,}600$ lbs-pulgs $= 7{,}299$ kg-m; pero la intersección de la línea vertical sobre 100 $p = 1.473$, con la curva de puntos ($n = 15$) para $f_c = 500$ lbs por pulg cuadrada $= 35$ kg por cm cuad **, da $M_c / bd^2 = 101$; y $M = M_c = 101\ bd^2 = 101 \times 8 \times 20^2 = 323{,}200$ pulgs-lbs $= 3{,}723$ kg-m.

**19 f.** Se notará que, en estos casos, **un aumento de 166.5 0/0**, en la cantidad de acero, ha **aumentado el momento de resistencia** (que todavía depende del concreto) en menos de 38 0/0; y el acero, en el caso 2, trabaja sólo como con 8,000 lbs por pulgada cuadrada $= 560$ kg por cm cuad ó la mitad de la fuerza máxima permitida (véase que la intersección de la vertical para 100 $p = 1.473$, con la curva de puntos para $f_c = 500$, es casi interceptada por la línea radial para $f_s = 8{,}000$). Véase § 13.

---

* *N. del T.* — Para convertir lbs en kilogramos, se multiplican aquéllas por .4536, y á la inversa, kg en lbs, se mult aquéllos por 2.204. Para convertir *lbs por pulg cuad* en kg por cm cuad, se multiplican aquéllas por .0703.

** *N. del T.* — 236,526 lbs-pulgadas expresan el momento de una fuerza de 236,526 lbs que tiene una pulgada de brazo de palanca; ó bien un brazo de palanca de 100 pulgs á cuyo extremo obra una fuerza de 2,365.26 lbs; y así se pueden cambiar el brazo de palanca y la fuerza siempre que el producto de ellos dé el valor 236,526 del momento dicho. Para encontrar, pues, el número de kilogramos que obrando con un metro de palanca den un momento equivalente, es necesario convertir las pulgadas del brazo de palanca en metros multiplicándolas por .0254 y las libras en kg multiplicándolas por .4536, ó sea multiplicar el momento en (pulgs-lbs) por el producto $.4536 \times .0254$, es decir, por la fracción .01152. Para convertir, á la inversa, en lbs-pulgs, se multiplican los primeros por 86.805.

**19 g.** En ambos casos, (1) y (2), la intersección de la línea radial para $f_s = F_s = 16{,}000$, con la curva de puntos para $f_c = F_c = 500$, daría (sobre un diagrama bastante amplio, exacto), $p = P = .004987$); $M/bd^2 = 71.5$ y $M = 71.5\ bd^2 = 228{,}800$ lbs-pulgs $= 2{,}636$ kg-m, el momento real, para los $b$ y $d$ dados, en el **caso ideal** en que $f_s$ y $f_c$ = respectivamente $F_s$ y $F_c = 16{,}000$ y 500.

## II. Diagrama.

**20 a. Recíprocamente, dado el momento de flexión**, 2,724 kg-m $= 236{,}500$ lbs-pulgs; $F_s = 1{,}120$ kg por cm cuad $= 16{,}000$ lbs por pulg cuad; $F_c = 35$ kg por cm cuad $= 500$ lbs por pulg cuad; de donde $P = .004987$, como antes. **Se pregunta el valor de b y d.**

Sean K y J = los valores de $k$ y $j$ respectivamente, que corresponden á $f_s = F_s$ y $f_c = F_c$.

Aquí tenemos :

$$Pn = 15 \times .004987 = .075;$$

$$K = \sqrt{(Pn)^2 + 2Pn} - Pn$$

$$= \sqrt{.075^2 + .150} - .075 = .3193;$$

$$J = 1 - K/3 = 1 - .1064 = .8936;$$

$$bd^2 = \frac{M}{F_s PJ} = \frac{2M}{F_c KJ} = \frac{2 \times 236{,}500}{500 \times .3193 \times .8963} = 3315.$$

**20 b. Un número infinito de áreas de sección**, $bd$, que dan el mismo momento de resistencia, M, pueden deducirse de $bd^2$.

**20 c.** Así, en el ejemplo del § 20 *a*, con $bd^2 = 3315$, tenemos

| $b$ | $d^2$ | $d$ | |
|---|---|---|---|
| 6 | 552 | 23.5 | |
| 8 | 414 | 20.3 | |
| 10 | 331 | 18.2 | etc., etc. |

**20 d.** Puede demostrarse (T. and M., págs. 175-6) que, dados M, las unidades de resistencia, y la unidad de precios, el **costo** de una viga de concreto armado, por unidad de longitud, varía á la inversa de $d$ en razón directa de $\sqrt{b}$, y en razón directa de $\sqrt[3]{b/d}$. En consecuencia, para un $bd$ dado, mientras más alta sea la viga, menor será el costo; pero consideraciones prácticas (tales como los límites prácticos para la reducción de $b$, etc.), restringen á menudo el límite á que puede llevarse en la práctica esta economía.

**21. Dentro del límite de los esfuerzos de trabajo permitidos**, fig. 2, los esfuerzos y las deformaciones, en las varias fibras, se suponen (hipótesis 1, § 4) proporcionales á las distancias á que están las fibras del eje neutro, como las representa el triángulo sombreado en la pequeña figura de arriba en los diagramas (triángulo que representa aproximadamente la porción inferior del área parabólica que se ve en la fig. 3); y tenemos, ecuación (7), § 10,

$$k = \sqrt{(pn)^2 + 2pn} - pn.$$

**22. Para esfuerzos que excedan de los esfuerzos de trabajo permitidos**, fig. 3, la hipótesis 1 es inadmisible, y debemos emplear toda el área parabólica, cuyo vértice corresponde con el máx de fuerza compresiva del concreto; así tenemos

$$k = \sqrt{(3pn/2)^2 + 3pn} - 3pn/2 \qquad (14)$$

La fig. 3 da valores de $j$, $k$ y $M/bd^2$, para valores máx de ruptura de $f_s$ y $f_c$.

**23.** Nótese que, para esfuerzos en el acero, $f_s$, que no excedan del límite de elasticidad usual y con $f_c$ máx $\leqslant$ 2,000 lbs por pulg cuad, es decir, $\leqslant$ de 140 kg por cm cuad, el **momento de resistencia máx ó de ruptura aumenta directamente con la cantidad** de la armazón hasta que ésta llega á 2 por ciento ó más. Así, la fig. 3, con $f_s = 30{,}000$ lbs por pulg cuad $=$ 2,100 por cm cuad, $f_c$ máx $\leqslant$ 2,000 (ó sea $\leqslant$ de 140 kg por cm cuad) $p = 0$ á 2 por ciento, tenemos $M/bd^2$ = aproximadamente á $25{,}000\ p$.

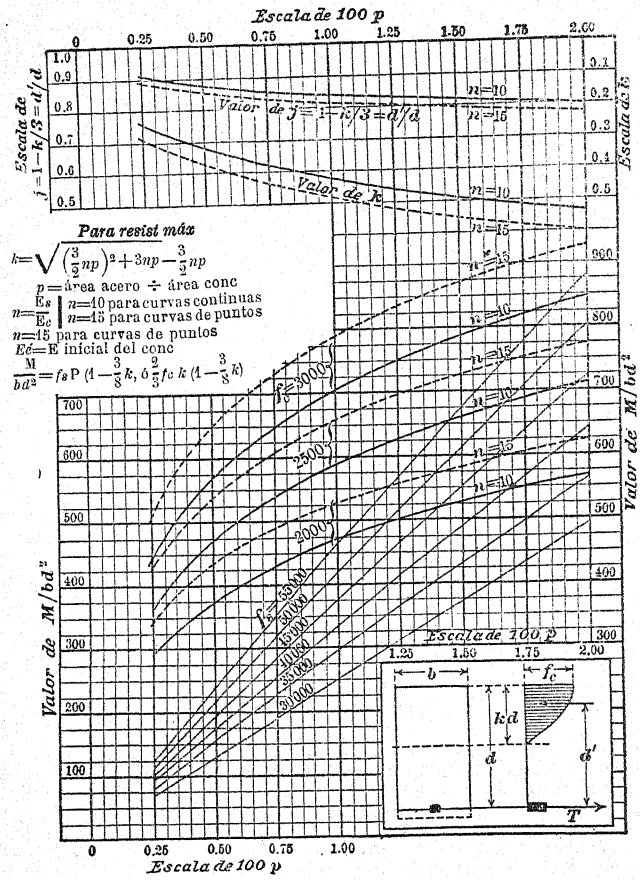

**Fig. 3.** Para esfuerzos de ruptura ó esf máximos. (Para fuerzas permitidas, véase fig. 2.)

$$k = \sqrt{\left(\frac{3}{2}pn\right)^2 + 3pn} - \frac{3}{2}pn, \qquad j = d'/d;$$

$f_s$=esfuerzo por unidad de superficie ó esf unitario en el acero, $f_c$=el mismo en el concreto y en la parte sup de la viga;

$p = a_s/a_c$=relación entre el área del acero y el área del concreto;

$M_s$, $M_c$=momento de resistencia, basado en el valor máximo permitido de $f_s$, $f_c$ respectivamente;

M=momento de resistencia, real

$$\frac{M}{bd^2} = f_s p\left(1 - \frac{3}{8}k\right) \text{ ó } \frac{2}{3}f_c k\left(1 - \frac{3}{8}k\right).$$

$n = E_s/E_c$. Las **curvas continuas** representan $n=10$; las **curvas de puntos**, $n=15$. Las **líneas de acero** para $n=10$; aproximadamente para $n=15$. $E_c = E$ *inicial* para el concreto.

## Secciones en T.

**24. Secciones en T** sencilla, fig. 4. $b$=ancho de la cabeza ó tabla; $b'$=ancho del alma; $t$=espesor de la tabla; $d$=diste de la parte sup de la viga al centro del acero; $kd$=altura del eje neutro; $d'=jd$=brazo de palanca de T y C.

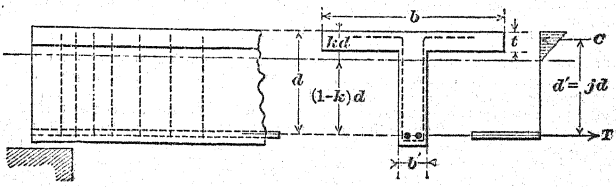

**Fig. 4.** Sección de una viga armada en forma de T simple. Teoría.

**25.** Cuando los topes de vigas rectangulares están unidos por losas, colocándose el todo de una vez y trabándose debidamente, el todo ó parte de la losa puede considerarse como una **tabla de compresión**, de cierto modo análogo á los ángulos y tablas de las vigas laminadas.

**26. El ancho de la losa,** $b$, fig. 4, que obra como tabla, se toma á veces igual á la distancia entre las vigas, pero no debe exceder de 1/3 de la luz de las vigas. Véase Especificaciones, §§ 168-178.

**27.** Un análisis exacto de tal sección es en extremo difícil, pero se cree que el siguiente **método** es racional y seguro.

**28.** Determínese la relación, $p=a_s/a_c$, del área de acero al área de concreto como si la viga fuese rectangular, con altura=$d$, y ancho=al ancho de la cabeza ó tabla, $b$. Con este valor de $p$, determínese la posición del eje neutro. Si éste cae dentro de la tabla ó cabeza ó cerca de su cara inferior, el momento de resistencia se encuentra exactamente como en el caso de cualquier sección rectangular. Véase Caso 1, § 19.

**29. Si el eje neutro cae por debajo** de la cara inferior de la tabla, la posición del eje neutro no será dada exactamente por la ecuación de las vigas rectangulares; pero la diferencia no será importante.

**30. El momento de resistencia** es $Cd'$ ó $Td'$, el que sea menor.

**31.** Ejemplos.

(1) **Eje neutro dentro de la tabla ó de la losa.**

Sea * $b = 1.50$ m $= 60$ pulgs; $b' = 20$ cm $= 8$ pulgs; $d = 50$ cm $= 20$ pulgs; $t = 12.5$ cm $= 5$ pulgs; esfuerzo máx permitido por unidad de superficie, $F_c = 35$ kg por cm cuad $= 500$ lbs por pulg cuad*; $F_s = 1{,}120$ kg por cm cuad $= 16{,}000$ lbs, etc., por pulg cuad; $E_c = 210{,}000$ kg, etc. $= 3{,}000{,}000$ lbs, etc.; $E_s = 2{,}100{,}000$ kg, etc. $= 30{,}000{,}000$ lbs, etc.; $n=10$. Supónganse 3 barras redondas de acero, diám 2.5 cm $= 1$ pulg.

Entonces

$$p = \frac{3 \times .785}{60 \times 20} = .002;$$

$$k = \sqrt{(pn)^2 + 2pn} - pn$$

$$= \sqrt{(10 \times 0.002) + 2 \times 10 \times .002} - 10 \times .002 = .18;$$

$kd = .18 \times 20 = 3.6$ pulgs;

$C = F_c bkd/2 = 500 \times 60 \times .18 \times 20/2 = 54{,}000$ lbs;

$T = 3 \times .785\ F_s$ = digamos 37,650 lbs.

Usando el valor más pequeño (el del acero) tenemos :

$M = Td' = T(d - dk/3) = 37{,}650\ (20 - 3.6/3) = 707{,}000$ lbs-pulgs $= 8{,}145$ kg-m .

* *N. del T.* — Véase *Obs. del T.*, § 18, pág. 1329, y *N. del T.* al pie de la misma página.

(2) **Eje neutro por debajo de la losa** **.

Sea $b = 1.5$ m $= 60$ pulgs; $b' = 25$ cm $= 10$ pulgs; $d = 75$ cm $= 30$ pulgs; $t = 10$ cm $= 4$ pulgs; $F_c$, $F_s$, $E_c$, $E_s$ y $n$ como en el ejemplo (1); 6 barras de acero redondas, diám $= 2.5$ cm $= 1$ pulgada. Entonces

$$p = \frac{6 \times .785}{60 \times 30} = .0026, \text{ y } k = .2; \; kd = .2 \times 30 = 6.$$

**32.** Puesto que la compresión unitaria *$= F_c = 35$ kg por cm cuad $= 500$ libs por pulg cuad, la fuerza, en el lado inferior de la tabla ó losa, es $500\ (kd - t)/kd = 500 \times 2/6 = 167$; y el **esfuerzo medio, en la tabla,** es $\frac{500 + 167}{2} = 333$ lbs por pulg cuad $= 23.3$ kg por cm cuad.

**33.** Las 2 pulgs (5 cm) del alma que están entre el eje neutro y el lado inferior de la tabla ejercen alguna resistencia á la compresión, pero ésta se desprecia, con un pequeño error del lado de la seguridad.

**34. La posición del centro de compresión** en la tabla puede encontrarse como si fuera el de un trapezoide; pero se acostumbra, y es seguro y suficientemente aproximado, suponer que está en el centro de la tabla, ó, en este ejemplo, á una distancia de $d - t/2 = 30 - 2 = 28$ pulgadas por encima del centro del acero. El momento de estas fuerzas es entonces $M = 333 \times 60 \times 4 \times 28 = 2{,}238{,}000$ lbs-pulgs $= 25{,}782$ kg-m **; pero, el momento de la resistencia tensiva del acero es solamente $M = 6 \times .785 \times 16{,}000 \times 28 = 2{,}110{,}000$ lbs-pulgs $= 24{,}307$ kg-m; y este momento, que es el menor de los dos, ha de tomarse como el momento real, M.

## Esfuerzo cortante.

**35. Esfuerzo cortante.** Además de los esfuerzos horizontales, á que resiste la compresión en el concreto y la tensión, en la armazón longitudinal de acero hay que atender á los esfuerzos cortantes verticales en vigas relativamente altas bajo cargas pesadas.

**36. Para el esfuerzo cortante total, V,** en cualquier sección vertical que dista $x$ de un apoyo, tenemos :

$$V = R - W \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (15)$$

donde R = á la reacción ascendente en el apoyo ;

W = el total de las cargas en la distancia $x$.

**37. El esfuerzo cortante vertical** se precave á veces empleando un gran factor de seguridad con el máx esfuerzo cortante del concreto, que se supone generalmente de 500 á 800 lbs por pulg cuad $= 35$ á 56 kg por cm cuad, mientras el esfuerzo cortante de trabajo está á menudo restringido á 30, ó 50 lbs por pulg cuad $= 2.10$ á 3.5 kg por cm cuad. Pero véase Estribos, §§ 38, etc.

## Armadura para el esfuerzo cortante. Estribos.

**38.** Cuando la carga produce un esfuerzo cortante que excede del límite supuesto para el concreto común, la viga se refuerza á menudo con **estribos** verticales, que consisten en barras ó varillas dobladas en forma de U, y que pasan por debajo de las barras horizontales y hasta cerca del tope de la viga; ó, en el caso de las vigas en T (fig. 4), dentro de las ramas horizontales ***.

**39. La distancia entre los estribos** se hace á veces tal, que dentro de una longitud horizontal $= d'$, haya en la sección un área agregada de barras de acero verticales suficiente para soportar el esfuerzo cortante vertical con la tensión unitaria permitida en el acero.

**40. Ejemplo.**

Considérese la viga en T del ejemplo (1), § 31, fig. 4; $b' = 20$ cm $= 8$ pulgs; $b = 1.50$ m $= 60$ pulgs; $d = 50$ cm $= 20$ pulgs; $k = .18$; $d' = 20 - kd/3 = 20 - 1.2 = 18.8$; momento seguro de resistencia, $M = 8{,}145$ kg-m $= 707{,}000$ lbs-pulgs. Sea la

---

* *N. del T.* — Compresión por unidad de superficie.

** *N. del T.* — Véase *Obs. del T.*, § 18, pág. 1329, y *N. del T.* al pie de la misma página.

*** *N. del T.* — Dice Marvá que, en las vigas T, sirven también para transmitir los esfuerzos á la unión de la rama horizontal con la vertical y que en toda clase de vigas son un correctivo *á las hiendas inclinadas* 45° que tienden á producirse cerca de los apoyos, como consecuencia del esfuerzo cortante.

luz L=6.10 m=20 pies=240 pulgs. Entonces, para una carga uniforme, tenemos W=8M/L=8×707,000/240=23,600 lbs=10,705 kg.

Esfuerzo cortante en los extremos W/2=11,800 lbs=5,352 kg.

Con un esf cortante de seguridad por unidad de superficie de 3.5 kg por cm cuad=50 lbs por pulg cuad, tenemos para la resistencia de seguridad del esfuerzo cortante del concreto común en la sección=50 $b'd'$=50×8×18.8=7,500 lbs =3,402 kg.

Bajo carga uniforme, este esfuerzo cortante ocurre á una distancia de los extremos,

$$= \frac{(11,800 - 7,500)\ L}{2 \times 11,800} = 3.65 \text{ pies} = 1.11 \text{ m.}$$

Deste este punto hasta el centro de la luz, puede el concreto soportar el esfuerzo cortante, y allí no se necesitan estribos. Pero véanse §§ 41, 45.

Entre este punto y cada apoyo supongamos que los estribos sean de 3/8 de pulg (10 mm) de acero redondo; el área de la sección transversal total de los dos lados de cada estribo=.22 pulg cuad.=1.42 cm cuad.

Concediendo 1,120 kg por cm cuad=16,000 lbs por pulg cuad, un estribo sostendrá 16,000×.22=3,520 lbs=1,141 kg.

El esfuerzo cortante total, 11,800 lbs=5,350 kg, en el soporte, dividido por 3,520, da 3.3 como **número de estribos** requeridos, en 18.8 pulgs=47.7 cm de longitud de viga; ó la **distancia, próxima á los extremos**, deberá ser $\frac{18.8}{3.3}$ = 5.5 pulgs=14 cm. Supongamos la carga, W, = 23,600 lbs=10,704 kg, uniformemente distribuída. Entonces, en un punto á 3 pies=.91 cm del extremo, $V = \frac{10 - 3}{10} \times 11.800 = 8,260$ lbs; 8,260/3,520=2.35; y la distancia entre los estribos=18.8/2.35=8 pulgs=20 cm.

**41. La distancia** puede hacerse **variar uniformemente** entre estos límites; y sería conveniente para el refuerzo vertical extenderse más allá del punto final teórico (3.6 pies=1.06 m del extremo; véase § 40) con uno ó dos estribos separados entre sí un pie=.305 m de distancia. Véase § 45.

**42.** Sean

A=Area total de la sección transversal vertical de las barras horizontales, en pulgadas cuadradas *;

L=luz, en pies *;

$z$=distancia entre el extremo de la viga y el estribo, en pies;

S=Area total de la sección transversal **requerida en los 2 miembros del estribo**, en pulgs cuads.

Entonces, cuando los estribos están á 1 pie de distancia,

$$S = \frac{4A}{L}\left(1 - \frac{2z+1}{L}\right) \qquad (16)$$

(J. W. Schaub, E. N., 03/abril/16, pág. 348.)

**43.** En general, el espacio entre los estribos $> d'$.

**44.** El concreto, en cada sección, debe obrar como un medio de conexión entre el refuerzo ó armadura horizontal y el vertical. También está sujeto á fuerzas compresivas al transmitir el esfuerzo cortante de un estribo al inmediato. La acción aquí es compleja, y **debe emplearse un factor suficiente de seguridad.**

**45.** A fin de proveer contra cargas excesivas que puedan obrar temporalmente sobre las vigas durante la construcción, es conveniente emplear estribos, aun donde no se requieran realmente para los esfuerzos cortantes determinados teóricamente, como se dijo antes. Siendo livianos los estribos, el costo de su empleo está principalmente en el trabajo de mano; de modo que si se necesitan, deben emplearse con liberalidad. Véase § 41.

---

* *N. del T.* — ara convertir cm cuadrados en pulgs cuad se multiplican aquéllos por .155; para convertir, á la inversa, pulgs cuad, en cm cuad se mult aquéllas por 6.45. Para convertir metros en pies se multip los m por 3.28, y para convertir pies en m se multip los pies por 0.3048.

## Esfuerzo cortante por unidad de superficie ó esfuerzo cortante unitario.

**46.** En cualquier sección horizontal de una viga, fig. 5, bajo carga uniforme ó central, las fuerzas horizontales de tensión ó de compresión aumentan desde los extremos, donde son cero, hacia el centro de la viga, donde alcanzan su máximo. En consecuencia, de dos secciones de plano vertical cualesquiera, 1 y 2, la sección 2, más próxima al centro de la viga, soportará los esfuerzos horizontales mayores.

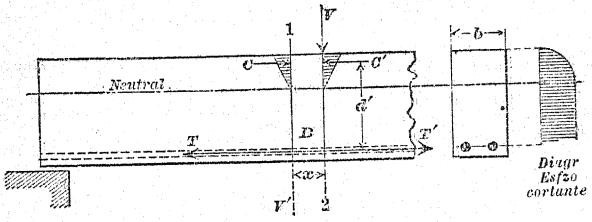

**Fig. 5.** Unidad de esfuerzo cortante.

**47.** Considérense las fuerzas como obrando sobre el cuerpo rectangular, B, entre las dos secciones 1 y 2.

**48.** En la sección izquierda, 1, el esfuerzo cortante vertical, V', procedente del soporte izquierdo, empuja á B hacia arriba; y la tensión, T, del acero hala á B horizontalmente hacia la izquierda; mientras la compresión total, C, que obra en el centro de las fuerzas de compresión, empuja á B hacia la derecha.

**49.** En la sección 2 de la derecha, el esfuerzo cortante vertical, V, empuja á B hacia abajo; mientras T' y C' están respectivamente en la misma línea que T y C, pero opuestas á ellas. Nótese que $T' > T$, y $C' > C$. Sea $T' - T = t$.

**50.** Supongamos que **no hay carga** sobre B. Entonces $V' = V^*$. Puesto que las fuerzas verticales distan $x$, su momento $= Vx = V'x$ *. El momento de $T' - T$ es $(T' - T)\ d' = td'$. En consecuencia, **para el equilibrio**, tenemos :

$$Vx = td'; \quad \text{ó} \quad t = Vx/d' \ldots\ldots (17)$$

**51.** En una viga de concreto armado, fig. 5, despreciamos la tensión del concreto. En consecuencia, la diferencia, $T' - T = t$, de tensión, entre las secciones 2 y 1, debe transmitirse, del acero al eje neutro, por un esfuerzo cortante total $= t$, uniforme * en cada sección horizontal; y, puesto que la sección horizontal del cuerpo, B, es $bx$, tenemos, para el **esfuerzo cortante** por unidad de superficie (ó esf cort unitario) ·

$$v = t/bx = Vx/d'bx = V/bd' = V'/bd' * \ldots\ldots (18)$$

### Esfuerzos diagonales.

**52.** Los esfuerzos de tensión longitudinales y los esfuerzos cortantes verticales y horizontales se combinan para formar esfuerzos **diagonales** que los reemplazan, y la armadura contra el esfuerzo cortante se determina más racionalmente encontrando, tan aproximadamente como se pueda, las direcciones é intensidades de estos esfuerzos diagonales resultantes (véase § 53), y colocando la armadura del mejor modo posible para resistirlos.

**53.** Del « Máximo esfuerzo por unidad de superficie en las vigas », pág. 523, tenemos, en vigas homogéneas, para **el ángulo**, A, entre el eje neutro y la normal

---

* **Si hubiese una carga**, L, sobre B (como, por ejemplo, en el caso de cargas uniformes), tenemos $V' > V$, y $V' - V = L$; y tendremos *dos* pares de fuerzas verticales, con los momentos respectivos siguientes : $Vx$ y $(V' - V)x'$, donde $x' =$ distancia de la sección 1 al centro de gravedad de L. Aquí tenemos, para la sección 1, $v' = V'/bd$ ; y para la sección 2, $v = V/bd'$.

resultante (tensión y compresión) ó esfuerzos « principales », $sp$ en cualquier punto:

$$\tan 2A = 2v/s; \quad \ldots\ldots (19)$$

y, para el **esfuerzo máximo**:

$$sp = s/2 + \sqrt{(s/2)^2 + v^2}; \quad \ldots\ldots (20)$$

donde $v$=al esf cort vertical ú horiz por unidad de sup y $s$=al mismo, pero de tensión ó compresión horizontal en el punto dado.

**54. Pero, despreciando el esfuerzo de tensión del concreto**, tenemos, en vigas con armaduras de barras rectas para tensión, y para puntos entre el eje neutro y el acero, $s=0$; de donde

$$\tan 2A = \infty; \quad 2A = 90^\circ; \quad A = 45^\circ;$$

$$sp = \sqrt{v^2} = v = V/bd'. \quad \ldots\ldots (21)$$

**55.** En consecuencia, entre el eje neutro y el acero, deberíamos poner armadura contra el **esf unitario de tensión**, $sp = V/bd'$, obrando en direcciones paralelas y formando ángulos de 45° con el eje neutro.

**56.** Esto se hace con preferencia por medio de barras, **colocadas como barras de tensión** de un puente de armadura de Pratt, figs. 7 *b*, 8 *b*, 9 *b*, págs. 751 y 752, y formando ángulos de 45° con la horizontal.

**57.** Generalmente, las barras de tensión, en cada extremo, en una distancia horizontal casi igual á la altura de la viga, se doblan hacia arriba para formar aproximadamente un ángulo de 45°, con el eje de las vigas.

## Adhesión. Véase pág. 1321.

**58. Unidad de adhesión.** Sean

$x$=una porción dada de la longitud de la viga;
$t = T' - T$=el aumento, en tensión total, T, en el acero y en la longitud, $x$;
U=el esfuerzo cortante vertical total en la sección transversal;
$d'$=la distancia entre T y el centro de compresión del concreto;
$U = t'x$=la fuerza de unión (ligazón), por unidad de $x$;
$m$=el número de barras;
$a$=la circunferencia de una barra
=el área de contacto circunferencial de una barra, por unidad de $x$;
$u = U/ma$=á la fuerza de unión, por unidad de $a$

Entonces (véase § 50), $td' = Vx$; $t = Vx/d'$; $U = t'x = Vx'x/d'x = V/d'$; y

$$u = U/ma = V/d'ma. \quad \ldots\ldots (22)$$

**59.** Para valores dados de la fuerza de unión, U, por unidad de longitud, y de la fuerza de unión, $u$, por unidad del área de contacto circunferencial, el producto, $ma = U/u$ (=área circunferencial total por unidad de longitud) para un caso dado, es constante; pero el área de la sección transversal, peso y costo de las barras aumentan como el *cuadrado* de $a$. En consecuencia, para una adhesión total dada, **son más económicas varias barras pequeñas** que menor número de barras más grandes; pero hay naturalmente, para cada caso, un límite práctico en esta economía.

## Vigas continuas.

**60.** Los sistemas de pisos se componen generalmente de losas y vigas continuas sobre soportes; y, si los momentos de flexión negativos sobre los apoyos (que producen *tensión* en el *tope* de la viga) se proveen ampliamente, con armadura cerca de la parte superior, y si los apoyos son inflexibles, ó exactamente de igual flexión, aprovéchase de ordinario la reducción en los momentos positivos de flexión (en el centro de la luz y cerca de él) debido á su continuidad.

**61.** Cuando se colocan losas de piso continuas sobre las vigas de apoyo, es corriente suponer $WL/10 = wL^2/10$ como momento máximo de flexión, donde L=luz; W=carga total sobre la luz; $w = W/L$=carga por unidad de L. Las vigas, continuas sobre los apoyos, pueden tener un valor semejante al empleado en el diseño, si las vigas están ampliamente reforzadas en su parte superior y sobre los apoyos.

**62. En cuanto á la seguridad**, se especifica frecuentemente que las vigas

las losas, etc., se considerarán como no continuas sobre los soportes, obligando esta práctica á prever, en el centro de la luz, contra momentos (positivos) de flexión mayores que si la viga fuese continua sobre los apoyos; pero, por otra parte, muy pocas vigas son totalmente no continuas; esto es: aun cuando la viga se supone no continua, hay momentos de flexión negativos sobre los apoyos, debidos al ancho del apoyo y á la carga en la viga sobre el apoyo. Tales momentos requieren armadura en la parte superior, sobre los apoyos y cerca de ellos.

**63.** En consecuencia, si bien es conveniente, en el caso de vigas no continuas, calcular el momento positivo de flexión central en el supuesto de absoluta no continuidad, las condiciones, aun de vigas no continuas, sobre sus apoyos, debe investigarse cuidadosamente y debe proveerse para los momentos negativos que allí se encuentren.

**64. Doble armadura.** La necesidad, en ciertos casos, de crear refuerzos contra los momentos negativos y contra momentos positivos (§ 62), obliga á colocar armaduras (fig. 6) cerca de la parte superior é inferior de la sección. Para mayor brevedad, aquel lado que, bajo momento positivo, sufre compresión, se llamará « armadura de compresión ».

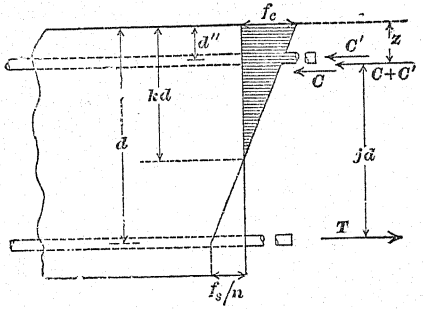

**Fig. 6.** Doble armadura.

**65.** Además de los símbolos del § 5, sean

$a_s'$ = área de la sección transversal del refuerzo de compresión;
$p' = a_s'/a_c = a_s'/bd$ = proporción del acero para la armadura de compresión;
$f_s'$ = esfuerzo unitario (por unidad de superficie) en la armadura de compresión;
$C'$ = esfuerzo total en la armadura de compresión;
$d''$ = distancia de la armadura de compresión á la cara más próxima de la viga:
$z$ = distancia de la resultante de las compresiones, $C+C'$, á la cara más próxima de la viga.

**66.** Entonces (despreciando la pequeña disminución de $a_c$; por la presencia de $a_s'$) para **la posición del eje neutro**;

$$k = \sqrt{2n\,(p+p'd''/d) + n^2\,(p+p')^2} - n\,(p+p'); \qquad (24)$$

**para la posición de la resultante de las compresiones:**

$$z = \frac{k^3 d/3 + 2p'nd''\,(k - d''/d)}{k^2 + 2p'n\,(k - d''/d)} \qquad (25)$$

**para brazo del par resistente:**

$$jd = d - z; \qquad (26)$$

**para esfuerzos de la fibra:**

$$f_c = \frac{6Mk/bd^2}{3k^2 - k^3 + 6p'n\,(k - d''/d)\,(1 - d''/d)} \qquad (27)$$

$$f_s = M/pjbd^2 = nf_c\,(1-k)/k \qquad (28)$$

$$f_s' = nf_c\,(k - d''/d)/k \qquad (29)$$

## Sistemas de armaduras.

**1.** La **teoría comúnmente aceptada** de vigas de concreto armado requiere armaduras de tensión longitudinal cerca del fondo * de la viga, y armadura de tensión diagonal á 45°, no sólo entre la armadura horizontal y el eje neutro, sino extendiéndose hacia arriba en la región de la compresión, á fin de aprovechar la adhesión superior debida á la compresión ejercida allí. Requiere también, generalmente, armadura de tensión cerca del tope *, en puntos situados sobre los apoyos ó cerca de ellos.

Véanse §§ 60, etc.

**2.** Se han ideado numerosos **sistemas de armazones** (pág. 1344) para atender á estas condiciones y se emplean mucho cuando las alturas de las vigas son suficientes y cuando la carga los exige.

**3.** Frecuentemente se sustituyen los **estribos verticales** por miembros diagonales ó se usan en combinación con ellos; ó se hace la armazón doblando simplemente algunas ó todas las barras horizontales del fondo * hacia arriba, de ordinario á 45° ó más ó menos.

**4.** Para **carga ligera** la armazón consiste simplemente en barras longitudinales cerca del fondo * de la viga.

**5.** Cuando la viga es á la vez delgada y ancha, como en las **planchas de pisos**, las pocas barras longitudinales, empleadas en la viga, se reemplazan (1) por barras numerosas y comparativamente delgadas, completadas por barras semejantes ó más ligeras, que las cruzan en ángulos rectos, soldadas ó atadas á ellas con alambre en sus intersecciones; ó (2) por un tejido, como la tela de alambre ó el « metal desplegado ». Véanse §§ 34, etc.

## Armaduras de barras.

**6.** Para un peso dado de metal, las **barras delgadas** dan mayor área de adhesión, y por tanto una adhesión total mayor que las barras más gruesas (§ 59, pág. 1337); y los esfuerzos se distribuyen sobre un área mayor de concreto. Además, empleando barras delgadas, una proporción mayor de metal puede bajarse hasta la distancia mínima permitida del fondo* de la viga. Dentro de ciertos límites, las barras delgadas se manejan más cómodamente que las gruesas. Las

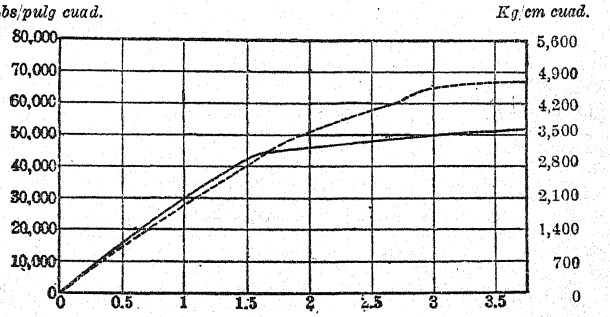

**Fig. 1.** La línea de puntos se refiere á barras torcidas, la continua á barras no torcidas.

barras usadas son rara vez $< 6$ mm ó $> 5$ cm de diámetro y varían por lo común entre 10 y 40 mm. En vigas altas, dos ó más hileras de barras delgadas son preferibles generalmente á una sola hilera de barras más gruesas.

**7.** En las armaduras verticales se doblan los **extremos libres de las barras** sobre la pieza, y los golpes accidentales sobre dichos extremos pueden transmitirse

*Los términos parte inferior ó « fondo » y parte superior ó tope se usan aquí refiriéndose á una viga sostenida en los extremos y cargada en la parte superior, y en la que la mayor porción del « fondo » está en tensión. En un *cantilever* es todo lo contrario.

á las partes ya incrustadas en el concreto, dañando su adhesión. Por este respecto son también preferibles las barras delgadas, porque transmiten menos los efectos de los golpes.

**8. Las barras de acero rico en carbón**, con sus altos límites de elasticidad, permiten el uso de secciones más pequeñas para un número de barras y un esfuerzo dado, pero son más frágiles (cuando son de calidad inferior) que las más blandas, y no se doblan fácilmente en frío para darles las formas deseadas. La pequeñez de las secciones comúnmente usadas y la protección que da el concreto hacen menos objetable la fragilidad en las obras de concreto armado que en casi toda otra obra en que se emplea el acero.

**9.** Puesto que el módulo de elasticidad del acero y del hierro laminados es casi el mismo (digamos 2,100,000 kg por cm cuad) para todas las clases, éstos se alargan todos lo mismo, por unidad de longitud, bajo unidades de esfuerzos iguales; pero el **acero con un límite elevado de elasticidad**, permitiendo el uso de secciones más pequeñas y á las que, por lo tanto, corresponden unidades de fuerza más altas, hace más probable el estiramiento, agrietándose en consecuencia el concreto; y además la contracción lateral del acero **pone en peligro la adhesión**. Por este motivo, se especifica á veces que, donde el límite de elasticidad excede de cierto mínimum (digamos 2,800 kg por cm cuad), se usarán barras torcidas, §§ 15, etc. A 2,100 kg por cm cuadrado, el acero se estira cosa de .10 por ciento; á 3,500, como .17 por ciento.

El trabajo en frío eleva el máximo de resistencia y el límite de elasticidad, pero baja un poco el módulo de elasticidad; véase fig. 1, que indica las pruebas hechas en el arsenal de Watertown (Pruebas de metales, 1904, pág. 397) sobre barras cuad de acero lisas y torcidas en frío, de 19 mm. Longitud estudiada 25 cm. La barra torcida tenía una vuelta en 20 cm. Resultados análogos se obtuvieron en las pruebas hechas en el arsenal de Watertown el 12 de julio de 1902 y publicadas por la Ransome Concrete Co. Véase § 21.

Las barras cuadradas de acero inferior se tuercen en caliente y son más frágiles.

**10.** Usanse muy generalmente en los E. U., para armaduras, las **barras de acero lisas redondas** y aún con más extensión en Europa. También se usan las **barras cuadradas**, pero son de manejo menos cómodo. Las barras chatas se han encontrado deficientes en la adhesión.

**11.** A fin de **aumentar la resistencia de las barras lisas** á su extracción del concreto, se doblan frecuentemente hacia arriba en ángulos rectos (ó á 180° de modo que formen un gancho) en sus extremos.

**12.** « El anclaje hecho por dobleces cortos en ángulo recto es menos eficaz que el de ganchos. » **J. C.**

**13.** Con el mismo fin (§ 11), pueden las barras aterrajarse en sus extremos y dotarse de **planchas de anclaje** de acero, aseguradas con tuercas. Estas planchas deben ser bastante grandes y gruesas para resistir los esfuerzos producidos por toda la fuerza de tensión de las barras. Al proyectar estas planchas supone el profesor L. J. Johnson una resistencia á la trituración, en el concreto, de 63 kg/cm cuad, y como resist de la fibra, en la plancha de anclaje, 1,750 kg /cm cuad. Varias barras juntas pasan á través de una gran plancha común, en cada extremo, que sirve también para mantener las barras en sus relativas posiciones mientras se coloca el concreto. Hay una importante previsión que consiste en colocar tuercas en el interior, que presentan á la plancha de anclaje un apoyo firme contra la acción de las tuercas exteriores. Se usan tales planchas en los muros, columnas, etc. De otro modo, y con el fin de darle cabida á la plancha de anclaje, la viga puede ahondarse en aquel lugar ó encorvar las barras hacia arriba cerca de sus extremos. Cuando se encorva hacia arriba, la barra ejerce una presión sobre el concreto, cerca del doblez. Esto aumenta la fricción en la porción doblada, y por ello reduce la tracción transmitida á la plancha de anclaje.

**14.** « Es preferible que la resistencia se deba á la conveniente adherencia en toda la longitud de una barra y no al anclaje del extremo. » **J. C.**

**15.** También para aumentar la adhesión (ó mejor dicho, para sustituirla por « una trabazón mecánica ») se usan « **barras deformadas** » de varios tipos.

**16.** La **principal ventaja** que se atribuye á las barras deformadas, es la de que la « trabazón mecánica » que producen, es la única seguridad de la armazón, después que la adhesión propiamente dicha se ha destruído, como sucede con una fuerza que exceda á la adhesión, por infiltración de agua, por golpes, durante ó después de la construcción, ó por constantes y rápidos cambios ó inversiones de carga en el trabajo. Las barras verticales especialmente, durante la construcción están expuestas

á golpes accidentales sobre sus extremos salientes superiores, y estos golpes pueden afectar la adhesión de las porciones ya incrustadas en el concreto.

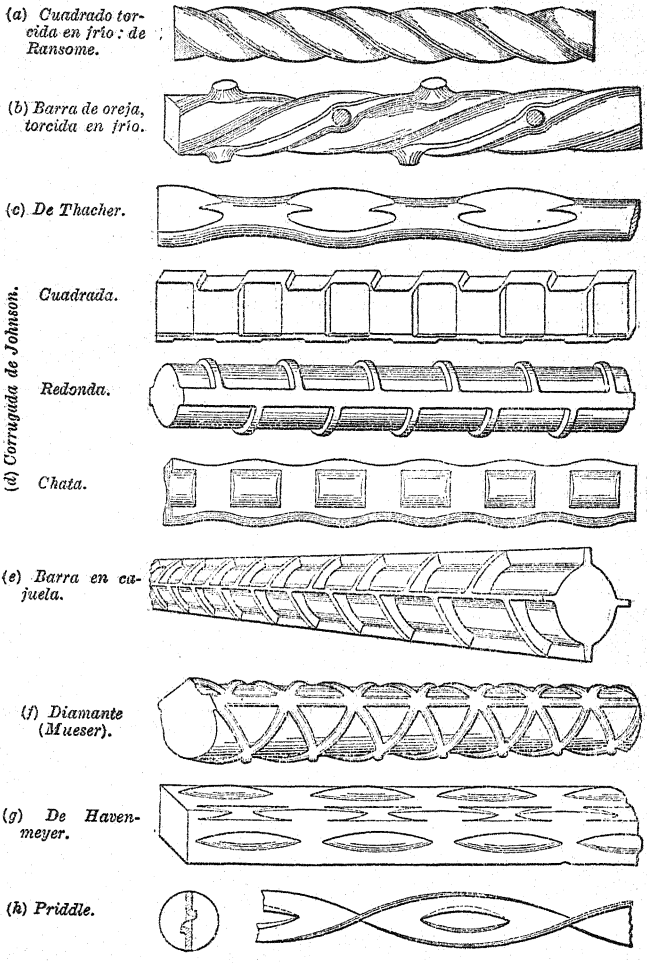

**Fig. 2.** Barras deformadas.

**17. Por otra parte,** se ha observado que numerosas construcciones hechas con barras lisas han resistido satisfactoriamente por años, en trabajos que producen aquellas vibraciones, y se pretende que cualquier ventaja que se derive de las barras deformadas está más que compensada por pequeño que sea el aumento de costo. Las

barras lisas están libres, por supuesto, de que se les pretenda patentar y siempre se encuentran de venta en el mercado.

**18.** Las proyecciones, en las superficies de algunas barras deformadas, pueden dañar la cubierta de concreto á menos que ésta sea de considerable espesor.

**19.** Al estudiar las pruebas comparativas de barras lisas y deformadas, debe prestarse atención á la riqueza de la mezcla del concreto; porque si éste no es bastante rico para lograr que cada barra quede completamente cubierta con cemento, la completa adhesión no se hará con regularidad y la prueba de extracción demostrará principalmente la diferencia con la « trabazón mecánica », en la cual, por supuesto, tendrán ventaja las barras torcidas.

**20.** « Las barras deformadas ofrecen medios apropiados para producir alta resistencia en las armazones. » **J. C.**

Las barras deformadas, figs. 2, tienen un uso más ó menos general :

**21. Ransome.** (*a*) Barras de acero cuadradas, torcidas en frío. Torcidas en el taller ó en el trabajo. (Son convenientes y económicas.)

**22. Barras de orejas torcidas en frío.** (*b*) Barra cuadrada, con ángulos redondos, para impedir la formación de grietas en el concreto, torcidas en frío. Las orejas están destinadas á resistir cualquier tendencia de la barra á destorcerse bajo tensión. Para efecto de trabajo en frío, véase § 9.

**23. Thacher.** (*c*) Barras redondas, deformadas achatándolas á cortos intervalos. El área de la sección transversal prácticamente constante. Cambios de forma hechos por medio de curvas graduales.

**24. Barras corrugadas**; (*d*) ordinariamente de acero con punto **cedente** (véase *N. del T.* § pág. 482*b*) 3,500 kg/cm cuad ó más. Cuadrada, redonda y chata.

**25. Barras de cajuelas** (*e*).

**26. Barra diamante.** (*f*) Laminada redonda, con dos proyecciones en espiral de igual paso y en direcciones opuestas (dividiendo la superficie en cuatro hileras de cajuelas con la forma de las facetas del diamante) y dos bordes longitudinales opuestos. El área de la sección transversal y el peso=los de barras cuadradas lisas de igual denominación. Ventajas que se le atribuyen : área de la sección transversal uniforme, estiramiento uniforme, distribución uniforme en la trabazón, los bordes proyectados ayudan á resistir la tensión; bordes redondos, sin tendencia á destorcerse bajo dicha acción.

**27. Barra Havenmeyer.** (*g*) Cuadrada con esquinas y proyecciones redondeadas.

**28. Barra Priddle** de trabazón interna. (*h*) Barra chata, perforada y torcida, y la ranura con rebordes, como se ve en la figura. Los tamaños pequeños trabajados en frío; los tamaños más grandes, en caliente. Puede formarse un tejido pasando barras más pequeñas, del mismo ó de otro dibujo, por las ranuras.

**29. La barra monolítica** consiste en una pieza de tensión horizontal con eslabones diagonales separados. En su sección la pieza horizontal semeja un carril pesado con dos cabezas en vez de una cabeza y una platina. Cada eslabón es una barra de acero redonda doblada en el extremo, formando así dos piernas diagonales paralelas, las que en la parte inferior se doblan horizontalmente, y estas partes horizontales se colocan en cada lado de la pieza horizontal que las agarra entre sus cabezas, retorcidas hacia adentro en esos puntos y con aquel objeto.

### Apoyos.

**30.** Es de la mayor importancia que las barras longitudinales de la armadura estén colocadas y se mantengan en sus **debidas posiciones**. Si al colocarlas definitivamente, quedan demasiado altas, su palanca de resistencia $d'$, y el momento de resistencia de la viga disminuyen. Si quedan demasiado bajas, tendrán debajo un espesor de concreto insuficiente para su protección. Varios sistemas se usan para mantener las barras en la debida posición.

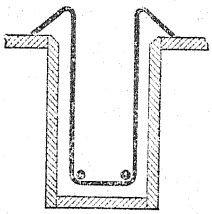

Fig 3.

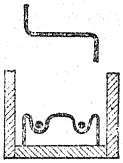

Fig 4.

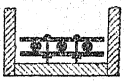

Fig 6.

Fig 5.

Apoyo para las barras de la armazón.

**31. Los estribos**, fig. 3, obran como apoyos colgantes para las barras principales.

**32.** A veces se sujetan las barras livianas con apoyos de alambre, fig. 4, ó con bloques de concreto, de 3 á 5 cm de espesor, fig. 5.

**33.** Las barras más pesadas pueden sostenerse con **abrazaderas**, fig. 6, hechas de hierro acanalado 2 á 2.5 cm, sujetas entre sí con pernos de cabeza redonda, de 6 mm á 10 mm de diámetro, colocados en las armaduras á 1.5 ó 2.5 m de distancia.

### Armaduras tejidas.

**34.** Usanse éstas en losas, planchas, etc., anchas y delgadas, en muros delgados, en cloacas y tuberías, en columnas, etc.

**35.** La forma más sencilla consiste en varillas en ángulos rectos y sujetas con alambre ó soldadas en sus intersecciones. Las barras más pesadas, ó principales, se colocan naturalmente de tal manera, que soporten los mayores esfuerzos. Las barras transversales mantienen las barras principales en su posición durante la construcción, y después distribuyen su tensión al través del concreto, ofreciendo así una trabazón mecánica. La malla debe ser bástante grande para dar paso á las partículas del agregado empleado en el concreto

**36. Jean Monier**, de París, empleó dichos tejidos para reforzar los arcos.

**37. Metal desplegado**, fig. 7. El acero laminado se ranura y se despliega en cuadriláteros. Las láminas tienen de 30 á 183 cm de ancho, de 2.44 á 3.60 m de largo; con mallas de 1½ á 15 cm.

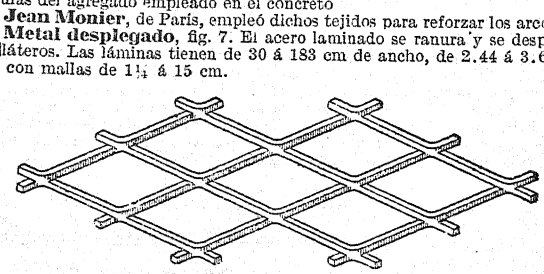

**Fig. 7.** Metal desplegado.

**38.** Cuando se emplea la armadura para losas en láminas cortas, éstas deben recubrirse lo suficientemente para transmitir la tensión de una lámina á la próxima. Este recubrimiento consume como el 10% del área del metal.

**39. Tiras metálicas de Clinton**, en cilindros de 30 á 60 m ó más, de alambres de acero estirados cruzándose en ángulos rectos, de 63 mm de malla, soldados eléctricamente, reforzados por cordones torcidos longitudinales, á 15 cm de separación y hechos cada uno de dos alambres engarzados y torcidos sobre cada cordón que cruza; y, cuando se desea, por atesadores transversales en forma de V de acero del escantillón n° 24, atados á los alambres á intervalos como de 20 cm. Se venden lisos, charolados ó galvanizados de 90 cm de ancho.

**40. Alambre soldado de Clinton**; alambre de acero estirado, n.° 3 á n.° 10 común ó galvanizado; malla, $7\frac{1}{2} \times 20$, $5 \times 30$, $7\frac{1}{2} \times 30$, $10 \times 30$ cm.

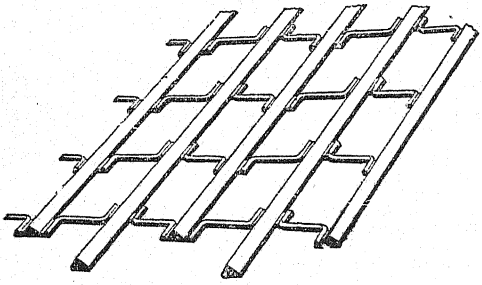

**Fig. 8.** Listoneado de metal.

**41. Listoneado de metal**, fig. 8; desplegado de planchas de acero especialmente laminado, con rebordes longitudinales. La malla varía de 2.5 en 2.5 cm. desde 5 hasta 20 cm. Las hojas son hasta de 4.80 m de largo.

**42. Otro tipo listoneado**, fig. 9.

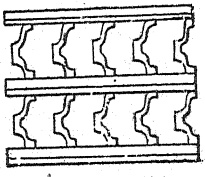

**Fig. 9.** Otro tipo listoneado.

## Armazones.

**43.** En general, las armazones son un poco más costosas que la simple armadura de barras comunes y, si se carga en piezas enterizas, sale más dispendioso su transporte y está más expuesto á sufrir en el viaje; pero tiene la gran ventaja de mantener las barras en su posición mientras se está colocando el concreto y de evitar el olvido ó la mala colocación de los estribos, etc., ya sea por accidente, ó voluntariamente. Las armazones pueden hacerse de barras comunes ó de barras torcidas. Deben estar provistas de medios de conexión por encima de los apoyos.

Sección transversal en el centro.

**Fig. 10.** Barra de Kahn.

**44.** En **las armazones de barras de Kahn**, fig. 10, las aletas laterales salientes están hendidas, en algunos lugares de su parte central, y dobladas hacia arriba, como se ve. La misma barra, invertida, se usa por encima de los apoyos.

**45.** La fig. 11 muestra la armazón llamada « Economy ».

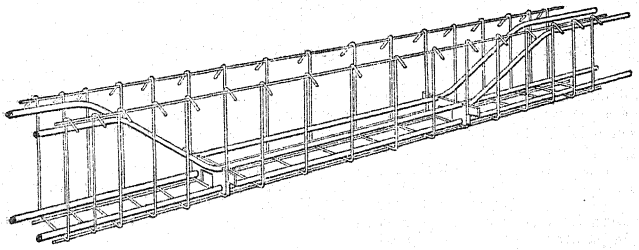

**Fig. 11.** Armazón « Economy

## Armazón con hierro de forma.

**46. El sistema Melan**, inventado por José Melan, de Austria Hungría en 1892, y patentado en los Estados Unidos en 1893, comprende un arco de concreto, en el cual van incrustadas vigas de hierro ó acero. Para luces pequeñas son de ordinario vigas laminadas en I, mientras que para luces considerables, consisten ordinariamente en cuatro ángulos unidos por celosías.

**47.** Cuando se incrusta en concreto una armadura de hierro de forma, de tamaño regular, para formar una viga, de modo que **el acero predomine** y suministre la mayor parte de la fuerza requerida, **el concreto obra principalmente como una cubierta protectora** para el acero; y el caso es apenas un problema de refuerzo propiamente dicho.

**48. Es difícil obtener un relleno perfecto**, con el concreto, en los espacios situados debajo de los rebordes de las formas laminadas ó armadas. En estos casos, cada día de trabajo debe terminar ó muy por encima ó muy por debajo del reborde, pues de otro modo la contracción, debajo de los rebordes, aumenta la dificultad.

## Armaduras para columnas.

**49.** Las columnas se arman por medio de **barras verticales**, colocadas cerca de la circunferencia y ordinariamente sujetas con alambre á intervalos, ó por **envoltura circular** (con sunchos espirales) ó con ambos.

Véase Columnas de concreto armado, pág. 1322.

**50.** En edificios altos las barras de las columnas se achatan á menudo en sus extremos para darles una buena superficie de apoyo y van unidas entre sí por dedales sueltos que mantienen á los extremos en el necesario contacto; debajo de los extremos de las barras, en la base, se coloca una plancha de hierro ó acero, para la distribución uniforme de la carga sobre el concreto de los cimientos.

**51.** En el sistema llamado **mushroom** (¿hongo?), del Sr. C. A. P. Turner, para columnas y pisos, las columnas se ensanchan en sus cabezas, para aumentar el área de apoyo, y la armadura del piso consiste esencialmente en piezas derechas (horizontales ó casi horizontales), que salen de las columnas y unidas, á intervalos, por piezas circulares ó poligonales, que cruzan las radiales generalmente en ángulos rectos. Se prescinde de las vigas y costillas y el piso es de espesor uniforme. Véase E. N., '09, febrero 18, pág. 178.

# EXPERIENCIAS Y PRÁCTICA

**Índice de los resultados seleccionados** de las págs. 1351, etc.

Las palabras en tipo de **letra negra**, que preceden á un punto y coma, se refieren á uno de los dos asuntos mencionados; las palabras en tipo común, que siguen á un punto y coma, al otro. Los numerales y letras se refieren á los informes de los ensayos, etc.

**Ejemplo.** Bajo **ARENA** (más abajo), « **Arena, naturaleza**; densidad del mortero, 8 *c*, *e*; 9 *d*, 86 *c* » se refiere á los Ensayos 8 *c*, etc., que informan sobre el efecto de (1) naturaleza de la arena, sobre (2) la densidad del mortero. Recíprocamente, en la pág. 1188, encontramos « **Mortero, densidad de** —; naturaleza de la arena, 8 *c*, *e*, 9 *d*, 86 *c* ».

# EXPERIENCIAS Y PRÁCTICA

## Resultados seleccionados.

Véase Índice, págs. 1346, etc.

## Orden de las materias.

Los elementos y condiciones característicos en la manufactura del concreto y las cualidades y conducta de éste, son tan numerosos y están tan estrechamente ligados entre sí en los informes sobre las experiencias, que ha sido imposible agruparlos satisfactoriamente ni en el cuerpo del texto, ni en el resumen que sigue.

La mayor parte de nuestros « resultados escogidos » van, por consiguiente, colocados aquí, siguiendo un orden aproximado al de las fechas de su publicación, y acompañados de un Índice, págs. 1346, etc., por medio del cual puede encontrarse prontamente cualquier asunto especial. El Índice está dispuesto racionalmente (esto es, no alfabéticamente), y, hasta donde es posible, en el orden que se sigue en el texto (págs. 1268 á 1294; 1295 á 1345), que se refieren al cemento, arena, mortero, agregado y concreto, común y armado. Los asuntos á que se refiere cualquiera de los informes publicados, llevan un número común, y, bajo este número común, están indicados por letras los varios paragrafos. Estas letras también distinguen generalmente varias características que abarca el número común.

Así, bajo Experiencia 8, tenemos un número de conclusiones alcanzadas por R. Feret; bajo 8 *a*, conclusiones respecto de la fuerza del mortero afectada por la proporción del cemento y la fineza de la arena; bajo 8 *c*, conclusiones sobre la porosidad y permeabilidad afectadas por la fineza de la arena y la riqueza del mortero, etc.

En el Índice, los punto y coma, en general, se usan para distinguir dos materias diferentes pero relacionadas entre sí. Así, « **Resistencia** fineza de la arena » y « **Arena, fineza de** —; resistencia », se refieren á secciones que dan informes respecto del efecto de la fineza de la arena sobre la resistencia del mortero ó del concreto.

**2. John C. Trautwine**, Cartera del Ingeniero Civil, 1872.

**2 a. Arena, densidad; humedad, compactación.**

**Muestras.** Arena pura ordinaria de la orilla del mar, tanto seca como húmeda (no mojada), véase tabla. La arena B era de grano mucho más fino que A. C se componía de los granos más finos cernidos de B.

**Tratamiento.** Las arenas secas eran compactadas por sacudimiento y trepidación perfectos; las arenas húmedas por apisonado en capas delgadas.

**Resultados.**

| | Arena A (gruesa) | | | | Arena B (más fina) | | | | Arena C (la más fina) | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | seca | | | húmeda | seca | | | húmeda | seca | | |

— 4 —

**4. Eliot C Clarke.** A. S. C. E. Trans, Apr, '85, vol. 14, pág. 163. Expts for Boston Main Drainage Works.

**Resultados.**

**4 a. Arcilla.** La agregación de arcilla sin exceder una parte para 2 de cemento dió una pasta « **más densa, plástica é impermeable**, propia para enlucir superficies ó para tapar las juntas que se filtren », y en general no influye notablemente en la **resistencia** de los cementos Portland y naturales. Las mezclas hechas con arena que contenga 10% de marga presentaron una resistencia normal á los 6 y 12 meses, aunque sólo dieron una resistencia de la mitad en el primer mes. La arcilla en el cemento es un « polvo casi impalpable cuyas partículas son bastante finas para llenar los espacios interiores del cemento ».

**4 b.** Un año de saturación en agua **dulce ó salada** en contacto con **roble, pino duro, abeto, ó haya**, no afectó los morteros.

**4 c. La sal**, ya sea en el agua que se usa para la mezcla, ó en la que se coloca el cemento, retarda un poco la **fragua**, pero no afecta notablemente la **resistencia**.

**4 d. Consistencia.** El exceso de agua retarda la **fragua**. Los cementos naturales necesitan más agua que el **Portland**; el de **polvo fino** más que el ordinario; el de **fragua rápida** más que el lento.

**4 e. Mientras más fina es la arena**, menor es la **resistencia**.

**4 f.** Con arena, **los cementos de grano fino** son más fuertes, los de **grano grueso** son más fuertes cuando están puros, especialmente los **Portland**.

**4 g. El Portland** resistió al rozamiento mejor cuando se mezcló con dos partes de arena, el natural con 1 parte. La resistencia disminuye rápidamente con pequeñas variaciones en aquel'as proporciones.

**4 h. En la fragua los morteros se dilatan** > 1 parte en 1,000.

**6.** E. Carey, Inst. de Ing. Civil Procs, vol. 107, pág. 55.

**6 a. Ácido sulfúrico** : Resistencia. El cemento puro ligado con agua que contenía 5% de ácido sulfúrico, tenía á los 7 días solamente 27% de la **resistencia** del cemento puro mezclado con agua sin ácido.

— 7 —

**7. Dr. Wilhelm Michaelis**, Inst. de Ing. Civil. Procs., vol. 107, págs. 372, 375.

**7 a. La desintegración** del cemento poroso en **el agua de mar** se ha demostrado que se debe á la acción de los ácidos sulfúricos é hidroclórico (muriático), que contienen los sulfatos de magnesia y los cloruros del agua de mar. Estos ácidos dejan la base más débil, la magnesia (que se deposita en la forma de hidrato) se combina con la cal del cemento, dilatando y desintegrando el concreto.

— 3 —

**3. R. Feret.** Anales de Puentes y Calzadas, serie 7.ª, tomo IV, '92.

**3 a. Resultados. La resistencia** del mortero aumenta con la cantidad de cemento, y en general (especialmente al principio del endurecimiento), con el tamaño del grano de la arena.

**3 b.** Los morteros varían mucho con la **porosidad.** Compárense 9 *d*, 9 *e*.

**3 c. La porosidad aumenta**
con la finura de la arena;
con la riqueza del mortero.

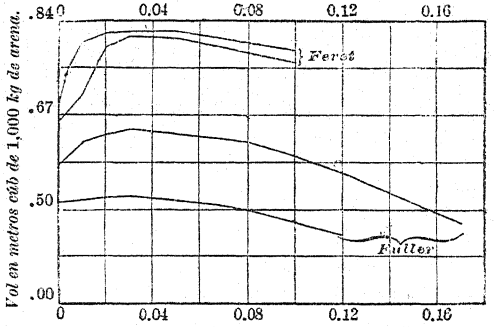
**3 d. La permeabilidad aumenta**
con el grosor de la arena;
con la riqueza del mortero.

**3 e.** Los morteros hechos con una mezcla **de arenas fina y gruesa** son menos porosos y menos permeables que los otros.

**3 f. La permeabilidad** de los morteros sujetos á la filtración continua de agua dulce ó de mar, **disminuye rápidamente,** pero en ciertos casos, el mortero se desintegra ó se agrieta.

**3 g.** Para evitar la desintegración en **el agua de mar,** úsese bastante arena gruesa y mucho cemento. Mézclense húmedos.

**3 h. Densidad de la arena.** Humedad y apisonado, fig. 1.



*Kilogramos de agua por kilogramo de arena seca.*

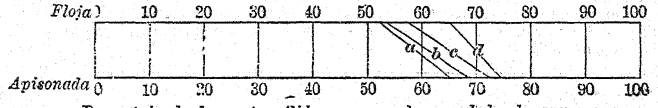
**Fig. 1.** Agua y apisonado.

(*N. del T.*— Llamemos (1) y (2) respectivamente, la curva superior é inferior de Ferret y lo mismo para Fuller.)

M. Feret empleó (1) una arena muy fina de duna y (2) una arena más gruesa de mar. Wm. B. Fuller, E. N., jul., 31, 1902, pág. 81, usó arena de ribera, (1) floja y (2) apisonada.

Según estos resultados parece que la agregación de agua afecta el volumen de la arena * de dos modos opuestos : (1) introduciéndose entre las partículas de la arena, aumentando de esta manera el volumen para un peso dado, (2) disminuyendo la fricción entre los granos y permitiéndoles que tomen con más facilidad la posición de mayor contacto, lo que disminuye el volumen.

Cuando se agregan pequeños volúmenes de agua solamente, parece que el primero de estos efectos prevalece, aumentando la masa hasta que la cantidad de agua llega á ser de 2 á 5% del volumen de arena seca. Con más agua prevalece el efecto lubricador, y el volumen disminuye.



*Percentaje de la parte sólida en un volumen dado de arena.*

**Fig. 2.**

**3 i. Figura del grano y compresión,** fig. 2.

Véase la nota al pie de la pág. 1283.

**Para el índice**, véanse pág. 1346, etc.

**Muestras.** De cuatro materiales como sigue :
*a*. Arena granítica, granos redondeados; *c*. Conchas quebradas;
*b*. Cuarzo molido, granos angulares; *d*. Residuo de *b*, granos laminares.
Cada uno de los cuatro materiales, cernido á la misma combinación granular, á saber, *c*, .5; *m*, .3; *f*, .2 **. Véase p. 1283.

**Resultados.** Véase la fig. 2.

**8 j. Efecto del tamaño del grano**, fig. 3.

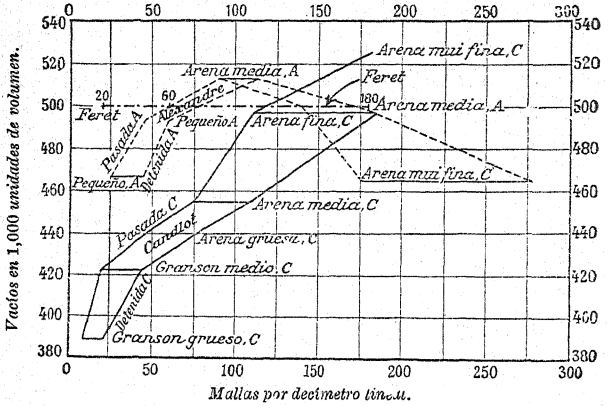


**Fig. 3.** Tamaño y densidad. **A** = Alexandre; **C** = Cand.ot.

Teóricamente, la densidad de una arena * ó granzón * compuestos de granos de tamaño *uniforme*, debería ser independiente del tamaño *absoluto* (§ 29, pág. 1286), pero los ensayos han dado resultados contradictorios, que demuestran variaciones sin importancia en la densidad en relación con el tamaño. Por ejemplo (T. and T., pág. 170), si la arena (excepto los tamaños muy finos que pasen por un cedazo de 30 mallas por cm lineal) y la piedra quebrada con partículas de tamaños irregulares de *forma* próximamente igual, se separan en porciones que contengan partículas de tamaño *uniforme*, estas diversas porciones darán un percentaje aproximadamente igual de vacíos. Esto está de acuerdo con los ensayos de R. Feret. (T. and T., págs. 171 y 142), fig. 3, según los cuales cada uno de los tres tamaños (grueso, mediano y fino) ** contenía 50% de vacíos. Los resultados del Sr. Feret están representados por la línea horizontal en la fig. 3. Por otra parte (fig. 3), M. Candlot (Feret, Anales de Puentes y Calzadas, 1892, 2.° sem) encontró que los vacíos aumentaban continuamente, y M. Alexandre (ídem) encontró que aumentaban primero, y disminuían después, al disminuir el tamaño.

**8 k. Efecto del tamaño de los granos, y de la cernida ó apisonada. La arena** suelta * tiene densidades que varían de .525 á .610, y su densidad es máxima cuando se mezcla 60% de arena gruesa ** con 40% de arena fina, sin arena mediana. En **la arena cernida, de manera completa** varían de .600 á .793, ocurriendo la mayor densidad en una mezcla de 55% de la gruesa con 45% fina, sin mediana.

---

* Véase la nota al pie de la pág. 1283.

**9. Luigi Luiggi y Valentino Cardi,** « Esperimenti sulle Calci, etc. », Genio Civile, Roma, '93.

**Porosidad, permeabilidad,** etc., **Cargas de seguridad.** Doce años de ensayos en relación con los trabajos del puerto de Génova, Italia.

**Resultados.**

**9 a.** En el mortero, **los vacíos se deben** parcialmente al aire adherido á las partículas de arena y del agregado y en parte á la evaporación del agua que se usa en la mezcla.

**9 b.** En el mortero, **el volumen de los vacíos** puede variar de 12 á 46% del volumen del mortero.

**9 c. Mínimo de vacíos** (5%) en concreto formado con 410 kg de cemento Portland, 1 metro cúbico de arena mezclada, 1.625 metros cúbicos de granzón pequeño.

**9 d. La porosidad aumenta**
con la finura de la arena;
con la riqueza del mortero;
al máx con cemento puro.
Compárense 8 *c* y 8 *d*.

**9 e. La permeabilidad aumenta**
con el grosor de la arena;
con la pobreza del mortero;
el mínimo con cemento puro.

**9 f. El concreto** de 676 kg de cemento Portland, 1 metro cúbico de arena mezclada, 1.625 m cúb de granzón pequeño, mezclado con cuidado con el agua suficiente (como $\frac{1}{3}$ de m cúbico) para reunirlo, fué **impermeable** bajo 12 metros de presión (1.2 kg por cm cuad).

**9 g. El concreto** de 410 kg de cemento Portland, 1 metro cúbico de arena mezclada, 1.625 m cúb de granzón pequeño, formando un cilindro hueco con espesor de 63 mm, resultó **impermeable** bajo 4 metros de presión (.4 kg/cm cuad) y apenas permeable bajo 8 m (.8 kg/cm cuad). Cilindros semejantes de la misma mezcla, **sin el granzón,** se filtraron algo bajo 4 m y con mucha facilidad bajo 8 m.

**9 h. Carga de seguridad en la compresión.** En los pisos de los astilleros : 1 : 2 : 3 concreto de cemento Portland, arena y granzón pequeño, soportan 7.5 kg/cm cuad con un factor de seguridad = 15.

**16. Considère.** « Génie civil », '99.

**16 a. Ductibilidad.**

**Muestras y resultados :**

Cantilevers de concreto, 1 : 3, 6 cm cuad, 60 cm de largo, lado en tensión reforzado por 3 barras redondas de hierro de 4¼ mm de diámetro.

**Tratamiento.** Carga tal que el momento de flexión fué el mismo para toda las secciones transversales. En uno de los prismas, la carga aumentó hasta que la unidad de alargamiento=.002. Entonces cargas, =44 á 71 0/0 de esta carga original, se aplicaron 139,000 veces, volviendo el esfuerzo á 0 en cada vez.

**Resultados. Unidades de alargamiento,** .000545 á .00125, la resistencia se redujo muy poco. Pruebas semejantes de muestras no reforzadas dieron como unidad de alargamiento á la ruptura, tan sólo de .0001 á .0002; la armadura hizo, al parecer, que el cemento resistiese mucha mayor deformación que cuando no estaba armado. Pero véanse los Ensayos 36, 38.

**Para el índice**, véanse págs. 1346, etc.

— 17 —

**17. C. E. Fowler.** A. S. C. E., Trans., '99, vol. 42, pág. 117.

**17 a. Resultados. Proporciones**, suponiendo que

1 barril de cemento Portland = 3.8 pies cúbicos = .108 m cúb;

34 metros cúbicos de concreto = 27 metros cúbicos más ó menos después de apisonado.

Aquellos concretos cuyos volúmenes de piedra aparecen en tipo negro como (**1.00**) tienen sus vacíos llenos, ó más que llenos, y en los de tipo corriente como (1.04) los vacíos no están llenos y el concreto es poroso y deficiente en resistencia. (*N. del T.* — La tabla que sigue la hemos convertido al sistema métrico.)

| Proporciones. | Cantidades en un metro cúb de concreto. | | | |
|---|---|---|---|---|
| | Barriles de cemento. | Arena, metros cúbicos. | Piedra con 40% de vacíos en m cúb. | Piedra (m cúb) con 50 0 0 de vacíos. |
| 1 : 2 : 3 | 2.30 | .51 | **.87** | 1.05 |
| 1 : 2 : 4 | 2.07 | .47 | **.95** | 1.15 |
| 1 : 2 : 5 | 1.81 | .42 | 1.04 | 1.26 |
| 1 : 3 : 4 | 1.69 | .57 | **.83** | **1.00** |
| 1 : 3 : 5 | 1.51 | .52 | **.92** | 1.11 |
| 1 : 3 : 6 | 1.35 | .48 | **1.00** | 1.20 |
| 1 : 4 : 6 | 1.30 | .55 | **.91** | 1.09 |
| 1 : 4 : 7 | 1.20 | .51 | **.97** | 1.17 |
| 1 : 4 : 8 | 1.08 | .47 | 1.03 | 1.25 |

Las cifras precedentes están de acuerdo con los resultados de la práctica. La columna para piedra con 40% de vacío representa muy aproximadamente la piedra caliza quebrada, que se quiebra en pedazos de varios tamaños, y la de 50% de vacío representa la roca volcánica, que se quiebra en pedazos de tamaño más uniforme.

**21 b. Densidad del concreto**; enteramente apisonado,

| | |
|---|---|
| Vol de 1 : 1 mortero, | Vol de concreto apisonado, aprox. |
| .33 × vol del agregado, | .91 × vol del agregado, |
| .40 × — — | .93 × — — |

**21 c. Densidad del agregado, compactación.** Piedra quebrada para pasar por un anillo de 5 cm y que tenía 43.3% de vacíos al sacudirla ligeramente en la medida, conservó solamente 37.4 % de vacíos, como término medio en 5 pruebas, después de haberla comprimido en la medida con pisón de hierro, aplicando con la fuerza ordinaria con que se apisona el concreto.

— 22 —

**22. Pruebas de los metales**, '00, págs. 1109, etc. Para los contratistas de la Compañía de la Planta.

**22 a. Muestras**; cemento Portland, arena, piedra triturada, 1 : 5 : 5. Piedra pasada por un anillo de 63 mm; los pedazos que pasaban por un anillo de 13 mm se separaron cerniéndolos.

**A, mezclado á mano; B y C mezclado con un mezclador portátil** de 2.40 m de largo, que se compone de una cajuela de acero, con varias hileras de espigas de acero, que bambolean. El agua de un tubo de regadera golpea el mezclador como en la mitad de su largo. Por consiguiente, el concreto se mezcla seco en la mitad superior, y húmedo en la inferior.

Piedra regada por parejo en una plataforma frente del mezclador.
Arena regada por parejo por encima de la piedra.
Cemento regado por parejo por encima de la arena.

El material se introduce luego en el mezclador.

**B.** Se deja formar una pila cónica, acumulando las piedras alrededor de los bordes.

* Consistencia : D = seco; P = plástico, E = exceso.

** Contracción = $\frac{100\,(A - C)}{A}$.

**Para el índice**, véanse págs. 1346, etc.

**C.** El material, al descargarlo, se niveló con escardilla.

Cubos de 30 cm; las vigas de 10×15, 15×15; 75 cm de luz. Todos, 2 días al aire, 2 meses en agua, 1 mes en el aire.

| **Resultados**; | **Cubos Resistencia á la compresión**, kg/cm cuad. | | | **Vigas Módulo de ruptura**, kg/cm cuad. | | |

**24 a. Acabado.**

Portales de túneles, Los Angeles, California, dos manos de 1 cemento : 4 arena; 1 pasta de cal.

Pedestales, ferrocarril de Chicago y E., Ill. R. R., 1 cemento : 1 arena. En buen estado.

Muelles, puente del río Arkansas, ciudad de Kansas, ferrocarril del Sur, dos manos 1 de cemento : 3 arena, una capa, 1 cemento : 1 arena : En buen estado.

1 de cemento : 3 arena : 1 pasta de cal, considerada como la mejor, debe evitarse excesivo cuchareo. El acabado debe conservarse húmedo durante dos semanas.

— 25 —

**25. Escuela Thayer.** Ensayos, '02. J. B. McIntire y A. L. True.

**25 a. Permeabilidad.** 97 ensayos, muestras de 25 cm de diámetro, 22½ de alto, tubo de 2 cm, se introdujo en 10 cm., Presiones (con agua) de 1.4, 2.8 y 5.6 kg/cm cuad durante dos horas. Todas las muestras de 30 á 45% 1 : 1 de mortero resultaron impermeables. Algunas con 40 á 45% de 1 : 2, y algunas de 1 : 2 : 4 y 1 : 2.5 : 4 fueron impermeables bajo presión de 5.6 kg. cm cuad 1 : 2 : 4 ó 1 : 2.5 : 4 recomendadas para presiones moderadas.

— 26 —

**26. Breuillé**, « Experimentos con el cemento armado », Anales de Puentes y Calzadas, '02, pág. 181.

**26 a. Corrosión y adhesión en el agua.**

**Muestras**; 4 planchas 90×99 cm, 30 cm de espesor, respectivamente de 599, 599, 798, 998 kg de cemento Portland, .327 m cúb de arena, .901 m cúb de guijarros, de 20 á 25 mm de diámetro. Barras de 5 mm de diámetro, colocadas á distancias diferentes de las superficies de las planchas.

**Tratamiento.** Las planchas se colocaron en agua y, de 12 á 15 m de profundidad, estas presiones se transmitieron sin disminución á los centros de los bloques. Las presiones se aligeraban de vez en cuando. El tratamiento se mantuvo por varios días. Después se dejaron los bloques al aire, expuestos á la intemperie.

**Resultados.** El metal se encontró perfectamente conservado, pero su superficie que era brillante, al colocarlo, se encontró mate al descubrirla después del ensayo, habiéndose destruído la adhesión donde había circulado el agua.

**26 b. Lustre.** Las barras de superficie brillante, colocadas en mortero de cemento durante varios días, tenían la superficie mate después que se les quitó el mortero, lo que indica una acción química entre el cemento y el hierro. Es probable que sea debido á esta acción que las barras pierden el moho cuando se colocan en mortero de cemento. La sal de hierro, que se forma por esta acción, la disuelve el agua que penetra hasta la superficie del hierro.

**26 c. Ganancia y pérdida en el peso.** Pedazos pequeños de hierro laminado, colocados en mortero de cemento, ganaron como .01% en el peso en 76 días. Puestas después en agua corriente, las láminas perdieron peso, lo que indica la solubilidad del compuesto cuya formación había aumentado el peso.

**26 d. Tiempo; adhesión.** Planchas de hierro, de 35×70×5 mm, fueron colocadas sobre concreto recientemente unido al mortero y éste (de 500 kg de cemento Portland por 1 metro cúbico de arena) fluía á la superficie. En varios períodos, estas placas presentaron un término medio de adhesión como sigue :

| | | | | | | |
|---|---|---|---|---|---|---|
| 2 | 7 | 12 | 17 | 23 | 27 | días. |
| .278 | .636 | .946 | 1.132 | 1.295 | 1.316 | kg/cm cuadrado. |

Los resultados de la prueba 26 *d* no se modificaron materialmente cuando el mortero había estado expuesto al sol, ó se había mezclado caliente ó muy mojado.

— 27 —

**27. G. Y. Skeels**, auxiliar del ingeniero de la ciudad, Sioux, Iowa, E. N., '02, noviembre 6, pág. 382.

**27 a.** Término medio de 2 y 4 probetas, 1 día al aire, 14 días en el agua. Cemento Portland.

Bajo **mezcla continua** durante 8 ó 10 horas, el mortero de cemento puro perdió como $\frac{1}{8}$ de su resist á la tensión; 1 : 2 perdió como $\frac{1}{6}$.

— 28 —

**28. Thomas S. Clark**, ingeniero residente, á cargo de la construcción de la Estación de Fuerza del ferrocarril de Manhattan, Nueva York. E. N., '02 julio 24, pág. 68.

**28 a. Retemple; resistencia.** El mortero de cemento natural puro, mezclado primero con 28 % de agua, mortero de cemento natural con arena con 14%. Retemplado una hora después de mezclado, « añadiéndole agua suficiente para volver á llevar la masa á su consistencia original ». Las muestras de un día, 3 horas al aire, las otras 24 horas. Las muestras retempladas presentaron, en general, más ó menos, la mitad de la resistencia normal.

Se obtuvieron resultados semejantes cuando se humedeció el cemento, cada 15 minutos durante una hora. En tales casos, en la práctica la resistencia aumenta algunas veces añadiendo un poco de cemento fresco.

Los morteros de cemento Portland retemplados después de una hora no presentaron deterioro notable, probablemente porque el cemento Portland se fragua más lentamente que el cemento natural.

— 29 —

**29. W. Purves Taylor**, A. S. T. M., vol. 3, pág. 376, '03.

**29 a. Edad, solidez. El envejecimiento** del cemento de polvo fino permite la hidratación de la cal libre, que casi siempre existe, haciéndolo inerte é impidiendo la expansión. Las muestras hechas con cemento de una semana, no estaban sólidas, pero al aumentar la edad del cemento, mejoró la solidez de las muestras hasta las 5 semanas, al cabo de las cuales estaban sólidas.

**29 b. Finura, solidez.** Las partículas más grandes del cemento molido grueso no se hidratan fácilmente. Un cemento cuyo 33% se retuvo en un cedazo n.° 200 y el 13% en uno n.° 100, se cuarteó y se agrietó en la prueba de ebullición, pero se hizo sólido al molerlo otra vez hasta que todo pasó por el cedazo n.° 100 dejándolo secarse durante dos semanas.

— 30 —

**30. La comisión del Gobierno francés.** Beton und Eisen, '03, vol. 5.

**30 a. Ductilidad.** Concreto 1 : 2 : 4. Los resultados fueron semejantes á los de Considère (véase ensayo 16 *a*). La ductilidad fué mayor cuando se endureció en el agua que en el aire.

— 31 —

**31. Chas. List**, Asociación de las Sociedades de Ingeniería, Diario, marzo '03, vol. 30, n.° 3, pág. 128.

**Para el índice,** véanse págs. 1346, etc.

**31 a. Efecto del agua de mar** en Guatemala, Centro América. Las pilas huecas, dentro del agua de mar se llenaron de concreto en que se había empleado el agua de mar para la mezcla. Una parte del mortero se filtró, y formó, con la arena circunvecina, masas de concreto que se adhirieron á las pilas. Al sacar las pilas se encontró el concreto en perfecto estado y fuertemente adherido á las pilas.

**31 b.** Cimientos de un puente de ferrocarril construído en 1895. Concreto ligero mezclado con agua salobre y permaneciendo en ella. De calidad excelente en 1903.

**31 c. Remolida.** El cemento se importó de Hamburgo (Alemania), en barriles. El buque hizo agua; considerándose el cemento como perdido, se devolvió su valor. Se almacenó debajo del piso de un depósito de mercancías con los lados abiertos, expuesto á la humedad del suelo y al salpique del mar. El cemento se endureció en bloques tan duros que se empleó como cimientos para postes de madera en los edificios. Este cemento en trozos, se trituró tan delgado como fué posible, mezclándolo con arena de playa menuda y agua salobre. El concreto estaba perfectamente duro á los tres días y se usó en los cimientos de puentes en agua salobre.

— 32 —

**32. Geo. W. Lee. Jr,** E. N., 1903, marzo 19, pág. 246.
**Acabado.**

**32 a.** Ferrocarril Central de Nueva York. **Armaduras** (pino de 5 cm con machiembrado) cubiertas con una mano de **jabón blando,** las aberturas en las juntas rellenas con **jabón duro.** El concreto se depositó y se sacó de las armaduras con una pala de punta cuadrada, mortero de 1 : 2 á lo largo de las armaduras. Después de quitar las armaduras, y mientras el concreto estaba todavía blando, se alisó la superficie con un movimiento circular, con pedazos de ladrillos blancos refractarios, ó de ladrillos de 1 cemento : 1 arena : se humedeció luego la superficie, y usando mortero líquido de 1 : 1 se la frotó y alisó con una regla de madera.

— 33 —

**33. Wm. B. Fuller,** A. S. C. E., Trans., 1903, junio, vol. 50, pág. 454.
**Acabado.**

**33 a. Estanque de concreto** armado en la planta de filtros, N. J., de 3.05 m de diámetro, 13 m de alto, muros de 38 cm de espesor en la parte inferior, 25 cm en la superior, construído en 8 horas; todo el concreto puesto desde arriba, descendiendo así 13 m. Se mezcló muy húmedo, colocando 140 lit (una carga de carretilla) á la vez, removiéndolo simplemente al colocarlo. Impermeable por dentro como por fuera. Se omitió el encalado interior que se había pensado hacer, por creerlo innecesario. Las superficies lisas; no se vieron piedras ó huecos.

— 34 —

**34. Profesor C. E. Sherman,** E. N., 1903, novbre, pág. 443.
**34 a. Arcilla y marga: resistencia.**

Los cementos Portland Dyckerhoff (alemán) y Lehigh (americano) con **arena** que contenía de 0 á 15% de **arcilla y marga.** La resistencia, en general, **aumentó materialmente** con la proporción de arcilla y de la marga. Con 10 y 15%, la resistencia, á los doce meses, era de 15 á 50% mayor que con la arena limpia.

— 35 —

**35. Pruebas de los metales,** 1904, págs. 345, 387.

**35 a. Columnas de concreto, sencillas y armadas; máxima resistencia de compresión, s,** kg por cm cuadrado y **módulo de elasticidad,** E* kg por cm cuadrado.

* E tomada entre los límites de la resist á la comp como sigue, kg/cm cuad: Nos 1 y 17; 7 á 42 kg; 16, 42 á 70 kg; 19, 1 á 33 kg; todos los otros, 70 á 105 kg/cm cuad.

**Muestras.** Cemento Portland y arena; agregado, guijarros y piedra volcánica quebrada, de 1 á 4 cm, y cenizas. Las columnas eran de 32 × 32 cm × 2.44 m aproximadamente. Las barras de la armadura de 20 mm torcidas, « Tw »; 15 mm corrugadas, « Cr »; 20 mm Thacher, « Th ».

**36. F. E. Turneaure**, A. S. T. M., Trans, '04, pág. 504.

**36 a. Ductilidad.** Vigas de concreto armado reforzadas. Unidad de alargamiento del concreto, á la primera aparición del agrietamiento, .00010 á .00035, formado de muchas rajaduras pequeñas, que aparecieron cuando la presión sobre el acero era > 350 kg/cm cuad. Las vigas sencillas se quebraron (sin agrietamiento previo) con una unidad de alargamiento igual. Las grietas que correspondían á la unidad de alargamiento mínimo eran invisibles en el concreto seco, pero se percibieron en el concreto húmedo por la aparición de vetas angostas húmedas como de 3 mm de ancho. Un poco más tarde tenían la apariencia de hendeduras obscuras como cabellos.

— 37 —

**37. Profesor Bauschinger**, « Beton und Eisen », '04, vol. IV, pág. 193.

**37 a. Corrosión; adhesión;**

Fragmentos de planchas de concreto armado, quebradas, en la prueba '87; **se expusieron á la intemperie,** hasta que se examinaron en '92. Adhesión; concreto quebrado á golpes de martillo, rompiéndose solamente cerca de los golpes. Corrosión; acero, libre de óxido aun junto á las superficies de fracturas descubiertas.

**37 b. Estanque dañado por maltrato;** agrietado: la armadura quedó descubierta en algunas partes. Hubo oxidación solamente en las partes así descubiertas. La adhesión como en 37 (*a*).

**37 c.** Fragmentos de planchas Monier de 6 á 8 centímetros de espesor. Expuestas á intervalos, durante 4 años, á **aguas sucias de cloaca.** El concreto permaneció duro, la armadura libre de oxidación á 1 centímetro de la superficie descubierta; la adhesión excelente.

— 38 —

**38. A. Kleinlogel**, « Beton und Eisen », '04, vol. 2.

**38 a. Ductilidad.** Vigas de concreto armado de 15 × 30 cm de 220 centímetros de largo. 1 : 1 : 2, cemento, arena, piedra caliza. Conservados debajo de arena húmeda durante 6 meses. El momento de flexión constante en toda la parte que se midió. Unidad de alargamiento en el concreto; armado, .000148 á .000196; sin armar, .000143.

‡ Probetas hechas de concreto tomado en la obra.
§ Un lote de concreto muy bien mezclado en 80 segundos.
‖ Concreto tomado de la plataforma de mezclar. Quitándole las piedras mayores de 2 cm.
** Á fin de acercarse en lo posible á las condiciones del trabajo en la práctica, se dejó reposar el mortero 30 minutos más que en el tratamiento ordinario.
†† Pasado por cedazo nº 10.
‡‡ Agua en la proporción del agregado seco.

**40 a. El acero limpio al incrustrarlo.** 3 semanas de exposición.
En el concreto se encontró óxido sólo en donde existían vacíos y otros defectos.
**40 b. El acero se oxidó incrustado,** de 1 á tres meses de exposición. Los cambios en el tamaño del acero tuvieron lugar solamente en las partes en que el cemento se aplicó mal.

— 41 —

**41. John S. Sewell.** Acerca del Incendio de Baltimore, E. N., '04, marzo 24.
**41 a. Resultados.** « El concreto sufre más ó menos un **cambio molecular** en el fuego y se astilla ó desconcha. El cambio molecular fué muy lento. El material calcinado no se **desconchó** mucho, excepto en los ángulos cuadrados descubiertos. **La eficacia,** en conjunto, es grande. Es preferible á los **ladrillos** huecos comerciales para arcos de piso y planchas.
**41 b.** Columnas de concreto armado, vigas simples y laminadas, planchas para pisos, por lo menos tan buenas como las **piezas de acero** protegidas con los mejores ladrillos huecos comerciales.
**41 c.** El concreto de **piedra** se astilla más que cualquiera de otra clase, porque los pedazos de piedra contienen cavidades de aire y de humedad y los contenidos rompen la piedra al calentarse. **El granzón** es una piedra en que se ha eliminado la mayor parte de estas cavidades al quebrarlas. Es por consiguiente mejor que la piedra cuando el concreto deba soportar el « fuego ».
**41 d. « Los ladrillos quebrados, las escorias quebradas, las cenizas y las escorias del cemento** producen buen concreto resistente al fuego. »
**41 e. « Las cenizas** que contengan mucho carbón parcialmente quemado, son peligrosas, porque dichas partículas se quemarán por entero debilitando el concreto. Las cenizas de locomotora dañan el cemento además de ser combustibles. El concreto de cenizas es seguro solamente cuando se hace bajo una vigilancia muy rigurosa é inteligente. Pero cuando está propiamente hecho, con los materiales adecuados, es difícil que la mampostería de ladrillos lo supere en sus cualidades de resistencia al fuego, y nada lo supera en ligereza, en igualdad de circunstancias.»

**44. Edwin Thacher,** A. S. C. E., Trans., '05, vol. 54, págs. 425, etc.

**44a. Efecto del frío. Puente de arco de Melan,** en Mishawaka, Indiana, 3 luces, de 33.55 m cada una, construídas á temperaturas que variaban de — 18° á 13° C. Se introdujo **agua caliente** en el mezclador. El concreto se colocó al calor de la sangre, suficientemente caliente para derretir la nieve 48 horas después. El arco central se completó á la temperatura de — 4° C, más ó menos. Al día siguiente la temperatura descendió á — 18° C. Dos semanas más tarde una balsa de hielos se llevó la cimbra y dejó el **arco sin apoyo.** No se observaron malos efectos. El asiento tan sólo un poco mayor que en los otros arcos, cuyas cimbras se quitaron más tarde como es costumbre.

**44b. Acabado.**

Puente en Economowoc, Wis. La cara de mortero, 1 cemento : 1 de residuos de cerniduras de granito : 1 arena. Al segundo día después de terminado, se quitaron los moldes y se alisó la superficie con piedra blanda y agua.

Arco de Inman, Hohenzollern. 1 cem : 5 piedra caliza quebrada. Después de fraguar 12 horas se quitó el cemento suelto con agua y brochas.

Fábrica de Bórax de la Compañía del Pacífico, Bayonne, N. J.

Acabado imitando sillería de mollejón, introduciendo listoncillos de madera en las armaduras y preparando las caras con un martillo neumático. Un hombre pudo preparar de 28 á 56 m cuadrados en 10 horas, con máquina; de 9 á 18, á mano. Muy buen efecto.

« El Sr. Cummings obtuvo un buen acabado repasando la superficie con una brocha de alambre mientras el cemento estaba todavía blando. »

Viaducto del ferrocarril de Utica y valle de Mohawk, en Herkimer, N. Y., y viaducto sobre vías férreas en Jacksonville. Fla. « Un acabado muy fino. » Para un muro duro, humedézcase la superficie y aplíquese con brocha una mezcla delgada de mortero de 1 : 2. Frótese la superficie con un pedazo de piedra de amolar, quitando las marcas de las tablas, rellenando los poros y produciendo una espuma en la superficie. Pásese sobre esta espuma, antes que se seque, una brocha mojada en

* Véase § 4, pág. 1314.
** Inseguro.

agua. Para una pared blanda todavía (habiéndose quitado las armaduras antes de 7 días) úsese mortero líquido de cemento puro, en lugar del mortero de 1 : 2. El resto del procedimiento se hará como se dice arriba.

Usense armaduras lisas, depositando el concreto húmedo directamente contra ellas. Después de quitar las armaduras alísese la sup con una regla de madera usando sólo el mortero suficiente para llenar los poros y darle una superficie lisa.

**44 c. Corrosión.**

Chicago. Las barras de hierro de las planchas de concreto de piedra caliza que cubrieron las bóvedas de las aceras durante 8 ó 10 años, estaban libres de moho. E. L. Ransome.

Obelisco en el Parque Central, Nueva York. Pequeño pedazo de hierro colocado en el mortero sacado de la base. Brillante después de 2,300 años. Pernos de seguridad de hierro, del lecho de concreto de un faro en el estrecho de Mackinac, libre de moho 20 años después de colocado. Wm. Sooy Smith.

Puente sobre el río Osage, Mo. Pilas cilíndricas de hierro rellenas con concreto de cemento de piedra caliza de Louisville. El hierro estaba absolutamente libre de moho después de 7 años de servicio. Albert A. Trocon, E. R., vol. 38, pág. 273.

Barras de acero, láminas de acero y metal dilatado, incrustado en bloques de concreto de 7.5×7.5×20 cm, y el acero sin protección, todo incluído en cajas de hojalata, y expuesto durante tres semanas una parte al vapor, al aire y al bióxido de carbono, otra al aire y al vapor, otra al aire y al bióxido de carbono, y otra á la atmósfera del cuarto de pruebas.

**Conclusiones :**

El concreto debe ser denso y mezclado húmedo. El cemento puro dió una protección perfecta.

En el concreto de ceniza, la corrosión se debió principalmente al óxido de hierro, no al azufre.

El concreto de ceniza, si está denso y bien apisonado, es casi tan bueno como el de piedra.

El acero debe estar brillante al incrustarlo.

Se debe dar una mano de cemento al acero antes de incrustrarlo. De otra manera quedará más moho que acero en el resultado. Prof. Chas. L. Norton, Informe n.º 2 del Inspector de la Estación de ensayos de Ingeniería de Boston.

Grenoble, Francia. Tubería de agua de cemento armado, Monier, de 30 cm de diámetro 4 cm de espesor, armadura de barras de acero de 6 y 1.5 mm. 15 años en la tierra húmeda. La adhesión era perfecta. El metal estaba absolutamente libre de moho.

Berlín. Muro de retención de concreto armado. Después de 11 años de uso, se encontró el metal libre de corrosión, « excepto en algunas partes en que las barras estaban á 8 ó 10 mm de la superficie ». El efecto del concreto, en preservar el metal, no se debió á la exclusión del aire. « Aunque el concreto sea poroso y no esté en contacto con el metal en todos los puntos, se filtrará y neutralizará el ácido carbónico, impidiendo la corrosión. » S. B. Newbury, E. N., vol. 47, '02, abril 24, pág. 335.

Los eslabones del anclaje de un puente de suspensión construído parcialmente por Rœbling en '55. Se quitaron en 75. Estaban perfectos. G. Bouscaren, E. R., vol. 38, pág. 253.

El anclaje del puente de suspensión del Niágara. No había moho en las partes en que la piedra caliza no había estado en contacto con el metal y donde no hubo movimiento estaba en perfecto estado después de 25 años. L. L. Buck.

**46. Asociación nacional para la protección contra el fuego.** Informe de la Comisión, '05.

**46 a. Pruebas por fuego.**

**Muestras.** Vigas de 20×28 cm×1.83 m, cada una con tres barras redondas de acero lisas, de 2 in de largo, incrustadas á 2.5, 5, 7.5 cm de la parte inferior de la viga. Cemento Portland.

| Agregados. | | Mezclas. | | Vacíos, % |
|---|---|---|---|---|
| Granzón ordinario cernido..... | 1:2:3, | 1:2.5:5, | 1:3.5:7 | 35 |
| Piedra caliza < 32 mm..... | » | » | » | 42 |
| Granito rojo cernido < .40 mm. | » | » | » | 40 |
| Cenizas ordinarias..... | 1:2:5, | 1:2:6 | .... | .... |

Mezclados húmedos. Las muestras tenían de 45 á 48 días.

**Tratamiento.** Tres horas en el horno, temperatura 1038° á 1093° C.

**Resultados.**

**46 b. La conductividad** fué **más baja** en el concreto de **ceniza** y en los concretos más **ricos.** Por lo demás, los materiales no ejercieron efecto importante.

**46 c. La resistencia de las barras disminuyó** 25% á 410° C. Tiempo medio que se necesita para llegar á 410°; 2.5 cm de incrustación, 1 h; 5 cm, 2 h; 7.5 cm, 2.5 hs.

**46 d. El cemento no se quebró ni astilló** bajo el fuego, pero perdió prácticamente toda la resistencia á la profundidad de 10 cm de los lados y parte inferior, y todo él se ablandó perceptiblemente. El cemento y la mayor parte de la piedra estaban completamente calcinados en la superficie, disminuyendo su efecto en un espesor de 10 cm. En todos los casos, **apareció agua** en las grietas transversales de las vigas, especialmente en las mezclas más ricas y con la temperatura de 100° C.

**46 e. Recomendaciones.** Los materiales deben mezclarse bien, mojados por medio de máquina, y bien pisoneados. El incrustamiento debe ser < 5cm, en casos importantes 7.

— 47 —

**47. John H. Quinton.** Agrimensor geológico de los E. U. « Ensayos » con tubos de acero-concreto, en plan de trabajo, abastecimiento de agua é irrigación de los E. U. Estudio 143, '05.

**47 a. Permeabilidad.** Determinar la utilidad bajo presión de aquellos tubos, para el servicio de cultivo de tierras de los Estados Unidos.

**Muestras.** Siete tubos de concreto armado mezclados á mano, de 1.50 m de diámetro, 15 cm de espesor, 6 m de largo, cada uno hecho en una sección, uno de las mismas dimensiones en cuatro secciones. Los obreros eran hábiles. En 3 de los 7 tubos, y en 3 de 4 secciones del octavo, se usó cal en la mezcla.

Los tubos variaban mucho de contextura. Uno « parecía de aspecto arenoso y habría sido fácil hacer un agujero en él ». Otro era « sumamente duro ».

**Tratamiento.** Los tubos se probaron con y sin forro interior de cemento y arena, etc., con y sin pasta de cal. La lechada de jabón y alumbre de Sylvester (pág. 1013), la pintura á prueba de fuego P y B; se probaron otras pinturas, y la arcilla se removió con agua dentro de los tubos. Las presiones hasta 4.9 kg/cm cuad.

**Resultados.**

**47 b.** A pesar de todas las precauciones, los tubos se filtraron especialmente á lo largo de las uniones. **La filtración disminuyó mucho con la presión,** pues el agua al colarse llenaba los poros de una lechosidad, pero entretanto la filtración era suficiente para dañar la base de los tubos.

**47 c. Las mezclas secas** dieron un concreto más permeable.

**47 d.** Con los granzones **graduados cuidadosamente** fué difícil obtener una **distribución** uniforme de los diferentes tamaños.

**47 e. Consérvese el concreto en la sombra** durante la mezcla y colocación.

**47 f.** Las interrupciones en el trabajo son menos peligrosas con las mezclas **húmedas**. Al apisonar ó calafatear evítese que se **mueva la armadura**.

**47 g. Hágase la armadura** bastante fuerte para proteger el concreto de a tensión.

**47 h.** La mixtura de **jabón y alumbre** es ventajosa al hacer el concreto; pero la mezcla con yeso (2 cm espesor) es conveniente para el interior, puesta en dos manos, la primera con pasta de cal, para retardar la fragua, la segunda (que se aplica al secarse la primera) se alisará con la cuchara. Al secarse aplíquese una lechada espesa de cemento puro.

**47 i.** Los tubos de concreto armado no se recomiendan para presiones mayores de 20 m. Para cortas distancias tómense precauciones cuando la presión sea de 30 m.

**47 k.** Los tubos de cemento son **propensos á agrietarse**, especialmente á lo largo de las juntas, pero aun agrietados son más secos y más durables que los de otras clases.

**47 l.** Al quebrar los tubos **apareció** el moho en una barra solamente y en una superficie de 4 cm de longitud en donde caía una filtración. El tubo había sido forrado con mezcla que contenía sal amoníaco y limaduras de hierro.

— 48 —

**48. Considère**, « Beton und Eisen », '05 vol. 3.

**48 a. Ductilidad.**

**Muestras.** Mezcla 400 kg de cemento Portland, .4 de metro cúbico de arena, .8 de metro cúbico de cerniduras de piedra caliza. Vigas de 15 × 20 cm, 3 m de largo. El lado de la tensión reforzado con dos barras de hierro redondas de 16 mm y 3 de 12 mm. El momento de flexión fué constante en todo el largo medido.

**Tratamiento.** Una viga se conservó en agua, una debajo de arena húmeda por 6 meses.

**Resultados.** Unidades máx de alargamientos :

| | |
|---|---|
| Conservada debajo del agua..... | .00107 |
| — — de arena húmeda..... | .00050 |

No se descubrieron grietas, aunque la superficie se alisó con cemento.

**La resistencia no se había afectado.**

— 49 —

**49. R. Feret,** « Un Tratado sobre el concreto, simple y armado », por Taylor y Thompson, '05.

**49 a.** La acción dañina del **agua de mar** se debe principalmente al **ácido sulfúrico** de los sulfatos disueltos, por consiguiente el cemento debe contener tan poco yeso (sulfato de cal) como sea posible. El cemento Portland debe estar fallo de aluminio y de cal. La existencia del material puzolánico es ventajosa. El cemento debe ser denso é impermeable.

**52. Jas. C. Hain.** Ferrocarril de Chicago, Milwakee y St. Paul, E. N., '04 /abril 28, pág. 413. E. R., '05, enero 28, pág. 103. **Arena; tamaño y limpieza.**

**Muestras.**

**52 a. Arenas impuras.**

1 : 3 mortero de cemento Portland, hechos con

(*a*) arena de cuarzo de granos redondos y lisos, mezclada con fragmentos más grandes de conchas de piedra caliza, el 92% pasó el cedazo n.° 24, el 28% pasó el n.° 50;

(*b*) « arena superior de St Paul », 54% pasó el n.° 24; el 11%, pasó el n.° 50;

(*c*) « arena superior de Otawa ».

**Resultados:**

Resistencias relativas de tensión : (*a*) 100, (*b*) 137, (*c*) 107.5.

La arena (*a*) dió un concreto excelente en una pila de centro, en un puente giratorio.

1 : 3 Mortero de cemento Portland, con arena que contenía de 3.2 á 15% de arcilla; las resistencias fueron < con arena limpia. Con cemento natural 1 : 2 y Portland 1 : 2, los resultados fueron generalmente favorables á la arena más limpia.

La arena con 6% de arcilla, dió morteros más fuertes antes del lavado que después.

Las arenas á las cuales se les había agregado artificialmente de 2 á 20% de marga rica, dieron un mortero que resultó algo irregular, pero en general más fuerte que los de arena limpia.

**52 b. Arena fina, con yeso.** Una arena que pasó toda por el cedazo n.°100, 93% pasó el n.° 200 (por consiguiente más fina que la mayor parte de los cementos, véanse las Especificaciones), y que contenía 12% de arcilla, dió una mezcla de

* 1 % = como 1,800 gr $CaCl_2$ para 1 barril de cemento Portland.

cemento Portland de 1 : 3, que mostró á los 6 meses y 1 año, casi la misma resistencia á la tensión que los morteros semejantes hechos con « arena superior de Otawa »; pero esta mezcla resultaba más débil á períodos más cortos.

— 53 —

**53. Jas. C. Hain**, ingeniero de construcciones de mampostería del ferrocarril de Chicago Milwakee y St. Paul, E. N., 05, marzo 16.

**Aceites**. Pruebas por **Geo. J. Griesenauer.**

**53 a. Una probeta de cemento Portland puro**, de dos años, sujeta á inmersiones ocasionales en aceite de lámpara, empezó á desintegrarse á los 10 meses, pero no se encontraron estructuras de concreto recientes dañadas perceptiblemente por el aceite. **Un piso de concreto** sobre el cual se almacenaron aceites de alumbrar y de lubricar durante 6 años, no estaba aparentemente afectado. El aceite penetró como á 1.5 mm. Un pedazo de este piso puesto en aceite, durante 10 meses, estaba todavía sano.

**53 b. Cemento Portland**; puro, 1 : 3 arena, 1 : 3 de piedra caliza cernida, 18 probetas de cada una, 4 días al aire. Después se saturaban diariamente con aceite de lámparas, más tarde con menos frecuencia. Aparecieron grietas en las muestras de 1 : 3 á los 2 1/2 meses; en las muestras puras, á los 5 meses. Todas las probetas se desintegraron al fin.

**53 c. Cemento Portland: 54 probetas**, puras, 36 de arena 1 : 3. 7 días al aire. Después se saturaban diariamente con aceite, más tarde con menos frecuencia. Aceites que se usaban : extracto de manteca, aceite de ballena, de castor, de linaza hervido, petróleo crudo. El aceite de manteca desintegró la mayor parte de las probetas de 2 semenas á 2½ meses, pero algunas permanecieron sanas durante nueve meses. El aceite (animal y mineral, mezclados) produjo casi el mismo efecto. Los aceites de ballena y de castor afectaron solamente unas pocas probetas, mientras que el petróleo y el aceite de linaza cocido, no desintegraron ninguna. El petróleo disminuyó en algo la resistencia. El aceite de linaza cocido formó una cubierta de protección y no afectó la resistencia. Como regla general, las probetas puras cedieron primero. Las de piedra caliza y escoria cedieron más; las de piedra caliza y arcilla menos.

**53 d. Cemento de sílice**; puro, 1 : 1; 1 : 2; 1 : 3, arena. Una probeta de cada uno. 2 años en el agua, 20 días en aire caliente. En aceite durante 2 años. Las tres primeras probetas estaban sanas, 1 de (1 : 3) se desintegró.

**53 e.** El aceite de linaza, en el procedimiento de Sylvester (pág. 1266), la parafina y el silicato de sosa se aplicaron en **capas** á las probetas, pero **ninguna las protegió** de la acción de los aceites.

**53 f. Concreto rico**, bien hecho con materiales buenos, y bien fraguado y sazonado, es el que mejor resiste al aceite. En la práctica, las **estructuras de concreto** rara vez se saturan con aceite, como pasó con estas muestras.

**55. Profesor Ira H. Woolson.** E. N., '05 junio 1.

**55 a. Absorción.**

**Muestras.** Cubos de 20 cm, 1 : 2 : 4, de 3 semanas, secados al horno durante 13 días á 49° C.

Parte con arena de < 1% de marga; todo pasó al cedazo de 3 mm; 75% pasó el

**Para el índice**, véanse págs. 1346, etc.

cernidor de 8 mallas por cm. Parte con piedra caliza cernida en el triturador de 10 mm; el 87 0/0 pasó el cernidor de 6 mm; el 40 0/0 pasó el cernidor de 3 mm; arena y tierra suficiente para llenar los vacíos. La piedra pasó al anillo de 40 mm.

**Resultados.**

**Absorción media**; 4 horas, 2.87%; 24 horas, 2.95%; 48 horas, 3.33%.

No hubo diferencia notable entre **la arena y las piedras cernidas**.

— 56 —

**56. W. C. Hoad,** Universidad de Kansas, E. N., '05, agosto 10.

**Arcilla y greda; resistencia y absorción.**

**56 a.** Cemento Portland con (*a*) arena normal de Otawa, 1 : 3; (*b*) 2 á 20% de la arena se reemplazó por arcilla ó marga. A los 90 días las resistencias relativas eran, en general: (*a*) 100; (*b*) de 94 á 125.

**56 b.** Hasta el 6 ú 8% de arcilla ó marga, no hubo aumento en la **absorción** con marga; y como 10% de disminución, con arcilla. Con **mayores porcentajes**, la absorción aumentó algo.

— 57 —

**57. Eng News,** '05, septiembre 28.

**57 a. Permeabilidad.**

**Cisterna de cemento armado**, 341 m cúb. 1 : 2 : 4, cemento Portland, arena de río y granzón. Capa de 25 mm de **mortero en el fondo**. A los **muros** se les dió una lechada de tres manos con **cemento puro líquido**, con la consistencia de una crema, aplicada después de humedecer bien los muros. Cada mano se dejó secar 24 horas. Donde las paredes estaban demasiado húmedas, la lechada se cuarteó; donde estaban muy secas, la lechada no se adhirió. Durante pocos días después de llenarla, perdió 8 mm en profundidad por día. Está perfectamente impermeable desde entonces. La cisterna se construyó con el aire á una **temperatura menor de** — 7° C; pero se cubrió con tablas y se encendieron dos estufas de cok.

— 58 —

**58. Profesor Ira Woolson,** E. N., '05, noviembre 2.

**58 a. Flujo (?)** (*Flow*). (*N. del T.* — Así llama el autor esta prueba.)

**Muestras.** Columnas de 10 cm de diámetro, 30 cm largo, modeladas en tubos de acero de 3 á 6 mm de espesor, y dejándolas fraguar y permanecer en ellas 17 días; al cabo de ellos el concreto estaba muy duro. El concreto permaneció en los tubos durante las pruebas.

**Resultados.** Bajo cargas de 68,000 kg, las columnas en los tubos más gruesos se acortaron solamente < 6 mm, pero bajo cargas de 54,400 á 68,000 kg, las columnas, en algunos de los tubos más delgados, estaban dobladas, deformadas y acortadas en 88 mm. aumentando su diámetro de 10 á 12 cm más ó menos. *Al quitar los tubos, se encontró el concreto sin quebrarse, sólido y perfecto!*

**61. Sandford E. Thompson.** A. S. T. M., Procs., vol. VI, 1906, pág. 379.

**61 a. Consistencia; efecto sobre la densidad *, permeabilidad y resistencia á la compresión.**

Muestras para la densidad y la permeabilidad, de 21 días de edad; muestras para la resistencia á la compresión, de 5 $^1/_4$ meses.

**Muestras.**

Cemento Portland Atlas; arena de Newburyport, peso específico=2.65; piedra volcánica, peso específico=2.78. 1 : 2.3 : 4.6, por vol; 1 : 2 : 4 por peso.

| **Consistencia empleada.** | Agua, %** |
|---|---|
| **Seca.** Como tierra húmeda, el agua brillando en la superficie al apisonar duro | 5.4 |
| **Mediana.** Parecía mojada al mezclarla, no fluyó en la caja de mezclar. Trepidaba poco | 6.9 |
| **Húmeda** | 9.2 |
| **Muy húmeda.** Como sopa espesa, se asentó á nivel en la caja de mezclar. Se necesitaron cucharones para manejarla. Ligeramente más húmeda que la que se usa en los trabajos de edificios | 11.0 |
| **Sumamente húmeda** | 13.7 |

**Resultados.** (Véase fig. 5 y *Obs. del T.*)

Para una consistencia dada, el **percentaje de agua** depende de la naturaleza del cemento y del tamaño y sequedad de los granos de arena. Una arena fina, ó con muchos granos finos, puede necesitar dos veces tanta agua como la arena ordinaria.

(*Obs. del T.* — Los números verticales (fig. 5) á la izquierda, de 140 á 420 expresan kg/cm cuad. Los de 2,000 á 6,000, lbs/pulg cuad.)

* Densidad = vol de las partículas sólidas en la unidad de volumen del concreto.
** Percentaje del peso del cemento, arena y piedra

**Para el índice**, véanse págs. 1346, etc..

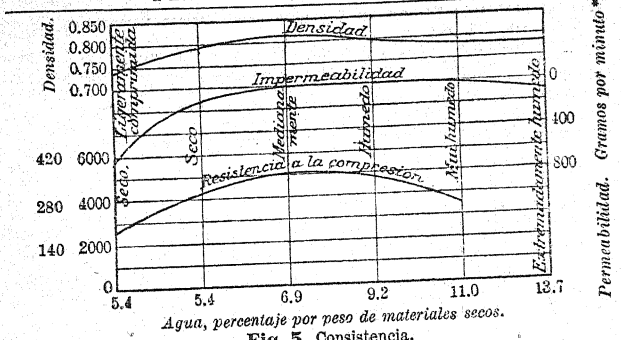

**Fig. 5.** Consistencia.

**61 b. Coeficiente de elasticidad.** 12 cubos de 30 cm, las deformaciones se midieron en un escantillón de longitud de 12.5 cm. Término medio de 4 muestras, 1 : 2 : 4, aproximadamente 1, 2, 6, y 17 meses de edad. Secas, 313,000 kg/cm cuad; medianas, 295,000; muy húmedas, 211,000. No hubo aumento apreciable con la edad en el coef.

**61 c. Edad; permeabilidad.** Los bloques se probaron á los 21 y 84 días, y mostraron permeabilidades, más ó menos de 2 : 1.

**61 d. El exceso de agua** arrastra el cemento fino, formando **lechosidades**, reduciendo la resistencia y aumentando la permeabilidad. **Espesor** de la lechosidad que se forma: 3 mm en las mezclas muy húmedas.

**61 e.** El **Sr. Thompson deduce** que en los trabajos de construcción y otros de cemento armado, el concreto debe estar suficientemente húmedo « para que fluya despacio por todas partes, incrustando muy bien el acero y haciendo que las superficies que dan contra los moldes sean lisas », y que el concreto mediano ó que trepida, es conveniente para las masas ordinarias de concreto, tales como cimientos, muros gruesos, arcos grandes, pilas y estribos.

— 62 —

**62. A. Blach**, E. N., '06 agosto 30, pág. 236.

**62 a. Naturaleza de la arena; resistencias y absorción.**

| **Muestras.** | Que pasa el cedazo n.º 170. |
|---|---|
| A, gneiss triturado, cernido por mallas de 12 mm..... | 90.8% |
| B, arena de Cowe Bay, que se usa mucho en Nueva York y sus cercanías..... | 95.8% |
| C, arena silicosa, fina limpia..... | 95.8% |

**Resultados.** De 7 y 28 días, 1 : 2 y 1 : 3 morteros, A y B dieron, en general, de 20 á 25% de **resistencias** de tensión y compresión, mayores que C. En general, las mezclas más fuertes fueron las más absorbentes.

— 63 —

**63. Alex. B. Moncrieff**, E. N., '06 agosto 30, pág. 227.

**63 a.** Probetas en el agua 2 años, en el aire 7 días y en aceite 6 meses. En general, el cemento puro perdió de 0 á 36% de su resistencia, mientras que el 3 : 1 ganó de 0 á 65 %. secándolo en el aire y sumergiéndolo en aceite.

**63 b.** Las probetas en el aire 7 días; luego 6 meses en aceite ó en agua. Las probetas de cemento puro en aceite resultaron de 0 á 55 % más débiles que las de cemento puro en agua y las probetas de 3 : 1 en aceite resultaron de 49 á 79 % más débiles que las que estaban en agua.

* Las pruebas de permeabilidad, á presión de agua de 5.6 kg/cm cuad.

**63 c.** Las probetas unas, 9 semanas en agua; otras 4 semanas; una semana al aire y 4 semanas en aceite. Con pocas excepciones, las probetas de cemento puro, en aceite, resultaron de 0 á 40% más fuertes que las que estaban en agua, mientras que las probetas de 3 : 1 resultaron de 0 á 63% más fuertes que las iguales que estaban en el agua. Muchas de las probetas tratadas por el aceite « se astillaron como pedernal ».

**64. Profesor Arthur N. Talbort.** Universidad de Illinois, Bull., vol. IV, n.º 1, '06 septiembre 1.

**64 a. Adhesión y fricción. '04.**

**Muestras y resultados.**

Mezcla, 1 : 3 : 6.

Tracción, en kg/cm cuad de sección neta;

Límite de elasticidad, en kg/cm cuad;

Adhesión, en kg/cm cuad de superficie incrustada:

(*N. del T.* Convertida al sistema métrico.)

| | Barras Johnson. | | Barras redondas. | | Barras cuadradas. | | |
|---|---|---|---|---|---|---|---|
| | ½" (12½mm) | ¾" (19mm) | ⅜" (10mm) | ¾" (19mm) | ⅜" (10mm) | ½" (12.5mm) | ¾" (19mm) |
| Tensión..... | 4,999 | 2,415 | 2,205 | 1,505 | 2,496 | 1,856 | 1,460 |
| Límite elasticidad. | 4,200 | 4,081 | 2,975 | 2,835 | 3,150 | 2,331 | 2,450 |
| Adhesión..... | 42 | 29 | 17 | 22 | 21 | 20 | 23 |

Con todas las **barras de Johnson**, las muestras se astillaron ó se quebraron. Todas las **barras lisas** se resbalaron. 6 de las 11 barras Johnson y 4 de las 11 barras cuadradas de 10 mm, « se golpearon 6 veces con una mandarria de 4.5 kg », reduciendo su adhesión en 5 á 20%.

**Muestras.**

**64 b.** '05-6. Cilindros de 15 cm de diámetro, 15 y 30 cm de largo, de 60 días. Mezcla de cemento Portland americano, resistencia á la tensión, puro, 51 kg/cm cuad á los 7 días; 1 : 3, 25 á 7 días, 37 á 75 días; arena gruesa de mortero; piedra caliza quebrada cernida por 25 mm. Metal, límite de elasticidad, kg/cm cuad. Acero dulce (D), redondo, 2,660; chato, 3,150. El cilindro de eje laminado en frío (C), 6,090. Acero de herramienta (T), 3,710.

**Resultados.**

| N.º de pruebas. | Acero. | Tamaño, mm. | Mezcla. | Largo incrustado, mm. | Kg/cm cuad de superficie incrustada. Adhesión. *a* | Fricción. *f* | *f*/*a* |
|---|---|---|---|---|---|---|---|
| 6 | D | 12.7 redondo. | 1 : 3 : 5.5 | 152 | 26.1 | 14.8 | .57 |
| 6 | » | » | 1 : 2 : 4 | » | 29.0 | 16.0 | .55 |
| 6 | » | 15.9 redondo. | 1 : 3 : 5.5 | » | 25.0 | 16.0 | .64 |
| 4 | » | » | 1 : 2 : 4 | » | 32.7 | 20.9 | .64 |
| 3 | » | 12.7 redondo. | 1 : 3 : 5.5 | 304 | 26.2 | 18.8 | .72 |
| 4 | » | » | 1 : 2 : 4 | » | 28.4 | 18.7 | .65 |
| 3 | » | 15.9 redondo. | 1 : 3 : 5.5 | » | 28.2 | 16.0 | .57 |
| 3 | » | » | 1 : 2 : 4 | » | 29.1 | 15.7 | .54 |
| 3 | » | 12.7 × 4.8. | 1 : 3 : 5.5 | 152 | 8.8 | 5.9 | .67 |
| 3 | C | 25.4 redondo. | » | » | 9.5 | 4.7 | .49 |
| 3 | » | 12.7 redondo. | » | » | 11.0 | 3.5 | .32 |
| 3 | T | 19.0 redondo. | 1 : 3 : 6 | » | 18.3 | ... | ... |

**La mezcla rica** es generalmente superior. **El cilindro de eje** laminado en frío y el **acero de herramientas** es generalmente inferior, debido á la uniformidad de sección y la lisura de la superficie.

**Para el índice**, véanse págs. 1346, etc.

— 65 —

**65. Jos. W. Elms**, químico, comisionado de los trabajos hidráulicos de Cincinnati, E. R., '06, octubre 27, pág. 467.

**65 a. Permeabilidad.**

**Muestras.** Cemento Portland y natural (de Louisville); arena de cuarzo del río Ohio, limpia, más bien fina, bastante uniforme en tamaño; piedra caliza cernida con mucho polvo y muy fino.

**Cubos de 75 mm.**

Cemento Portland; (*a*) 1 cemento : 2 arena, 10% de agua; (*b*) 1 cem : 1 arena : 1 cerniduras, 11% de agua; (*c*) 1 cem : 2 cerniduras, 14% de agua.

Cemento natural; (*d*) 1 cem : 2 arena, 15% de agua; (*e*) 1 cm : 1 arena : 1 cerniduras, 15% de agua; (*f*) 1 cem : 2 cerniduras, 17% de agua.

**Cilindros huecos**, 15 cm de diámetro, 20 cm de largo, el hueco de 5 cm. Cemento Portland y arena, 1 : 1 y 10% de agua.

**Tratamiento.** Agua (clara) llevada al centro de las muestras. **Cubos**, 1 día al aire, 6 en agua. **Cilindros**, 1 día al aire, 27 en agua, 4 al aire.

**Resultados.** La filtración pasó á través del mortero, de 4 á 5 cm de espesor. **Cubos**; bajo 3.5 kg/cm cuad mantenidos durante 3 á 16 horas, poca ó ninguna agua (máx=6.5 lit por m cuad) pasó por entre los cubos de cemento Portland; de 11.6 á 98 lit/hora/m cuad á través de los cubos de cemento natural. En el Portland la filtración se hizo apreciable con presión de 4 á 5 kg/cm cuad; en el natural, á 1 kg. Los cubos con arena de 1 : 2 resultaron los más permeables. **Cilindros**, 1 á 2 kg/cm cuad; filtración .00920 á 50 lit/hora/m cuad.

La filtración disminuyó muy notablemente con el tiempo.

**69. M. R. Barnett,** Instituto de Ingeniería civil, Procs., '07, vol. 167, pág. 153.

**69 a. Acción del agua dulce sobre el concreto de piedra caliza.** Acueducto de Thirlmere, agua potable de Manchester, Inglaterra. La sección del acueducto, construida con concreto de piedra caliza. Piso 23 cm de espesor, se redujo como en 6 mm en espesor, con apariencia de panal, carcomido en muchas partes, y con mucha filtración.

**69 b.** Las muestras de las piedras calizas, con que se hizo el concreto, se conservaron durante seis meses en agua dulce corriente, en el acueducto, y perdieron en peso de 6.8 á 18.1% por año, mientras que los bloques de muestra de cemento puro y de mortero de cemento Portland de 1 : 1, ganaron 5.5 y 3.6% respectivamente.

— 70 —

**70. Profesor Ira H. Woolson,** A. S. T. M., Procs., '05, pág. 335, '07, pág. 404.

**Temperaturas altas y conductibilidad térmica.**

**70 a. Mezcla,** 1 : 2 : 4; con ceniza, 1 : 2 : 5. Cemento de una mezcla igual de 3 Portlands. Arena aguda, de calidad menuda buena, «no especialmente limpia»; 90% pasó el cedazo de 5 mallas por cm. El agregado de ceniza de caldera de buena calidad, habiéndosele quitado la mayor parte de las cenizas finas; granzón de cuarzo limpio de 19 mm; trapa (piedra volcánica) triturada. Mezclada moderadamente húmeda, apisonada en los moldes hasta que el agua fluyó á la superficie.

**70 b. Temperaturas altas.** '05, pág. 335. Fig. 6.

**Muestras.** Para la resistencia á la compresión, cubos de 10 cm; para la elasticidad, prismas de 15 × 15 × 35 cm. 3 cubos y 3 prismas se probaron sin calentar; 3 cubos y 2 prismas de cada agregado (trapa y caliza) á cada temperatura.

**Resultados.**

**70 c. Módulo de elasticidad, E.** Para E, las curvas de trapa (roca volcánica) y de caliza casi coincidieron.

**70 d.** Después de calentarlos hasta 1093° y 1371° C, los cubos de piedra caliza aparecían sanos mientras estaban calientes, pero se **desintegraron al enfriarse.**

**70 e. Después de enfriarse** bajo 400° C, los prismas de trapa y de caliza estaban cubiertos de grietas diminutas. Bajo temperaturas más altas, estas grietas aumentaron en número y en tamaño, y los prismas se cimbraron y desintegraron al enfriarse bajo 816° C.

**70 f.** Las muestras de concretos de **trapa** (piedra volcánica) **y de cenizas** permanecieron **sanas,** mientras que las de concreto de **granzón** se **agrietaron** y desmoronaron, debido, probablemente, al gran coeficiente de **dilatación** del dirección y al hecho de que este coeficiente en una dirección es doble del de la cuarzo, perpendicular.

**Para el índice**, véanse págs. 1346, etc.

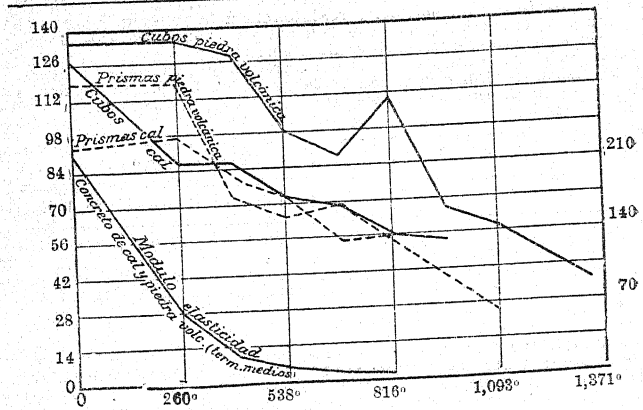

**Fig. 6.** Resistencia al calor; grados C.

(*N. del T.* Los números verticales á la izquierda, de 14 á 140, indican las cargas de trituración en kg/cm cuad. Los verticales de la derecha, de 70 á 210, el coeficiente de elasticidad en *miles* de kg/cm cuad.)

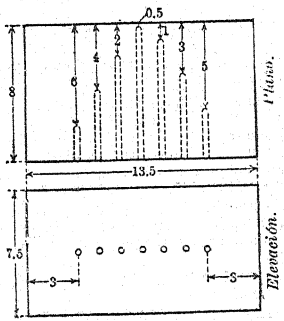

**Fig. 7.** Conductibilidad térmica.

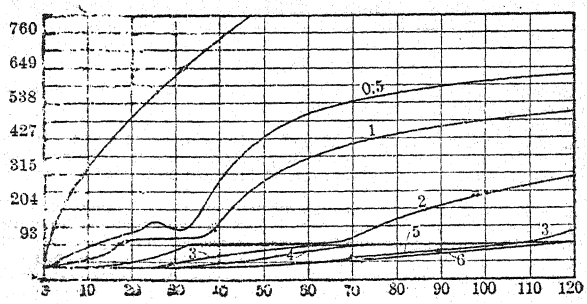
(Equivalencias de los números de la fig. 7 en **centímetros** : .5=1.25; 1=2.5; 2=5; 3=7.5; 4=10; 5=12.5; 6=15; 7.5=18.75; 8=20; 13.5=33.75.)

**70 g. Conductibilidad térmica.** '07, pág. 404. Figs. 7 y 8.

**Muestras.** Bloques de concreto, con agujeros como en la fig. 7. La mezcla igual á la de la fig. 70 *a*.

**Tratamiento.** Las muestras estuvieron en los moldes 24 horas, en el agua 48 horas, se conservaron húmedas durante 2 ó 3 semanas, dejándolas secar bien. Edad, en la prueba, como de 2 meses. Los bloques se colocaron á la entrada de la hornalla.



*Tiempo en minutos.*
*Roca volcánica (basalto).*

**Fig. 8.** Conductibilidad térmica.

(**Explicación de la fig. 8.** Los números verticales á la izquierda, de 93 á 760, son temperaturas C. La curva primera á la izquierda, sin número, traza las temperaturas del horno. Las curvas numeradas corresponden á la conductibilidad en las líneas marcadas con los mismos números en la fig. 7.)

**Resultados.** La fig. 8 indica, para una de las muestras de piedra volc, los tiempos, en minutos, que se necesitaron **para transmitir las temperaturas de las hornallas** por los diferentes espesores del concreto. Las curvas de descenso, en ó cerca de 200° F (m. ó m. 93° C), se atribuyen á la **generación del vapor.**

**70 h. El concreto** de 5 á 7 cm (si permanece en su lugar) **protegerá** el metal de la armazón en un incendio ordinario.

**70 i. El metal de la armazón descubierto** no conduce calor perjudicial á la parte incrustada.

**74. T. L. Condron**, de la Compañía Condron y Sinks, representante de la Compañía de metal dilatado y barras corrugadas, Diario de las Sociedades occidentales de Ingenieros, '07, febrero, vol. 12, n.° 1. Ensayos por el profesor C. E. de Puy, Instituto Lewis, Chicago.

**74 a. Adhesión; barras deformadas y sencillas.**

**Muestras.**

Cilindros de concreto, de 15 cm de diámetro, 20, 30, 40, 50, 60 cm de largo. Mezclados á mano, proporcionados con exactitud, 1 : 2 : 4, de cemento Portland, arena gruesa, piedra caliza quebrada, de 12 mm y menos, sin polvo. Bastante humedad, para que entraran en los moldes con facilidad removiéndolos con una varilla. Todo el concreto se mezcló en un lote. Los bloques de 20 y 40 cm tenían 25 días cuando se probaron, los otros 31 días. Las barras pasaron enteramente por los bloques.

**Resultados.**

| | Diám en mm. | Esfuerzo kg/cm cuad de superficie incrustada. Resbalamiento > .25 mm. — Incrustados. | | Resbalamiento > .8 mm. — Incrustados. | |

**76. J. L. Van Ornum**, Sociedad americana de Ingenieros civiles, Trans., vol. 51, pág. 443, '03/diciembre, y vol. 58, pág. 294, '07/junio.

**76 a. Fatiga.** Bloques de cemento puro en compresión. Las cargas repetidas producen fracaso si la carga es > que la mitad de la que se requiere para la trituración en una sola aplicación.

Vol. 58, pág. 294.

**76 b. Fatiga.** Como 600 pruebas.

**Muestras.**

Bloques de 12.5 × 12.5 cm y 30 cm de largo, en compresión, y vigas de 10 cm de ancho, 15 de alto, 1.80 m de luz, armadas con dos barras de acero lisas, de 12 mm en cuadro. Cada lote produjo 8 bloques ó 4 vigas. Mezcla de 1 : 3 : 5 en volumen. Cemento Portland americano corriente, probado según la especificación de la Sociedad americana de Ingenieros civiles (pág. 942). Arena del río Misisipí, gastada por el agua, más bien fina, 1,584 á 1,760 kg por m cúb; vacíos 30 á 38%. Piedra caliza quebrada, de las cercanías de San Luis, de 1,280 á 1,520 kg/m cúb, que pasó el cernidor de mallas de 4 cm; casi la mitad de las piedras eran mayores de 2.5 cm, como la décima parte menores que 1 cm. Vacíos 42 á 48 %. Vacíos, en 3 de arena + 5 de agregado, de 16 á 19%.

* Cubiertos con una capa delgada de moho, pero sin escamas. Las otras se tomaron frescas de los cilindros y estaban libres de moho.

** Johnson, fig. 2 (*d*), pág. 1341.

**Para el índice,** véanse págs. 1346, etc.

**Tratamiento.** Las muestras para la compresión se dejaron 1 día al aire en los moldes, las vigas por 2 días; después todo en agua por 2 semanas, después al aire, protegidas contra las corrientes, hasta que se probaron.

Las muestras para la compresión eran de 1 mes y de 1 año de edad, cargadas de 4 á 8 veces por minuto; las vigas, de 1 mes, 6 meses, y 1 año, cargadas de 2 á 4 veces por minuto.

**Resultados. El efecto en la proporción de la repetición** fué insignificante; pero se cree que aumenta rápidamente cuando pasa de 10 veces por minuto.

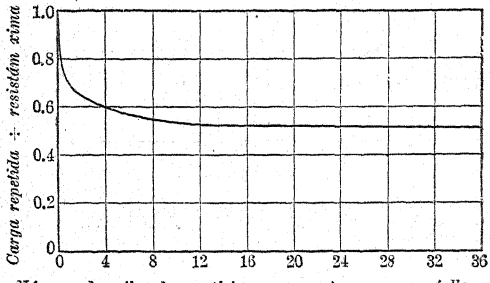

**Fig. 9.** Fatiga.

**Fatiga.** La curva de la fig. 9 representa bien los resultados que se obtienen en estas condiciones variables.

**76 c.** Al concreto repetidamente sometido á esfuerzos menores que el límite de fatiga es decir : á menos de la mitad del máximo del esfuerzo, véase figura), « se le comunicó un **límite definido de elasticidad**, dentro del cual las resistencias son proporcionales á los esfuerzos » (es decir : dentro de los cuales el **coef de elasticidad, E,** es constante).

**76 d. Fatiga y adhesión.**

**Muestras.** Barras de acero cuadradas sencillas de 15 mm, incrustadas en concreto como anteriormente. Las muestras se hicieron con gran cuidado, muy bien apisonadas.

**Tratamiento.**

2 días en los moldes, 7 días en agua, al aire 3 semanas. 30 muestras para la prueba de fatiga se sometieron á un « golpe y presión combinados, con su vibración consiguiente »; 150 golpes por minuto, cada golpe=8.18 kg-metro. Término medio, 50,000 golpes á cada muestra.

**Resultados. Adhesión** inicial media, 8.7 kg/cm cuad de superficie incrustada; **fricción** (después de deslizamiento), 6.3 kg/cm cuad. En **las muestras no fatigadas,** 10.5 y 7 kg/cm cuad respectivamente.

**76 e. Fatiga bajo carga continua.** 2 prismas de concreto permanecieron intactos durante 1 mes bajo el 90% de la resistencia á la trituración. « Unos pocos bloques de concreto fallaron en la prueba de compresión en pocas horas bajo una presión constante de un percentaje mayor. » Una viga de concreto armado falló en 10 meses bajo el 90% de su carga de ruptura.

**79. Wm. B. Fuller y S. E. Thompson,** Sociedad americana de Ingenieros civiles, Trans., '07, diciembre, vol. 59, pág. 67.

**Resistencia, densidad y permeabilidad.** Como las afectan las **proporciones y la naturaleza de la arena y del agregado.** Ensayos en el estanque del Parque Jerome, Nueva York.

**79 a. Muestras.** Cemento Portland como se recibió para usarlo en el estanque, agregado (1) piedra y cerniduras de mica esquistosa en los trituradores en el estanque, 35% de mica, que en el mortero ó concreto « no forma planos que afecten la resistencia seriamente ». (2) Granzón y arena de Cowe Bay, sacados con draga del río (« arena y granzón redondeados por el agua, completamente limpios y que se componían casi enteramente de partículas de cuarzo »; peso específico como 2.65). Tamaño máximo de la piedra, 6, 2.5 y 1 cm.

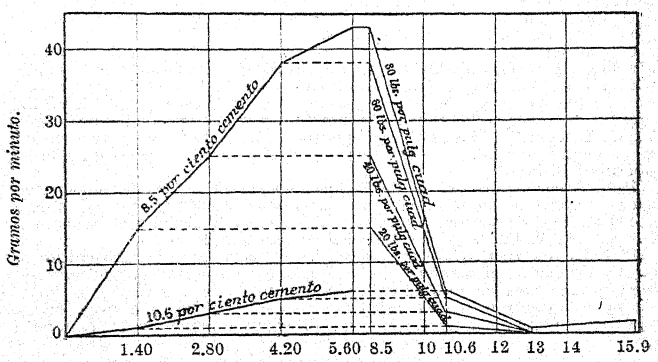

**Fig. 10.** Permeabilidad.

**Para el índice,** véanse págs. 1346, etc.

(Explicación complementaria de la fig. 10. Los números horizontales, de 1.40 á 5.6, son presiones en kg/cm cuad. En las líneas inclinadas que marcan presiones así: 80 lbs/pulg cuad=5.6 kg/cm cuad; 60 lbs/pulg cuad=4.2 kg/cm cuad; 40 lbs/pulg cuad=2.8 kg/cm cuad; 20 lbs/pulg cuad=1.40 kg/cm cuad.)

Las pruebas se hicieron con « **mezclas graduadas** » (dando con las proporciones la densidad mayor del agregado) y « **mezclas naturales** » (1 : 2.5 : 6.5, 1 : 3 : 6, 1 : 3.5 : 5.5).

**Resultados.**

**79 b. Tamaño del agregado; resistencia y densidad.**

| Tamaño mayor de la piedra..... | 5.7 cm. | 2.5 cm. | 1.2 cm. |
|---|---|---|---|
| **Resistencia relativa.** | | | |
| Compresión..... | 1.00 | .83 | .72 |
| Transversal..... | 1.00 | .91 | .77 |
| **Cemento que se necesita** para igual resistencia, relativa..... | 1.00 | 1.17 | 1.33 |
| **Densidad** relativa..... | 1.00 | .96 | .93 |

**79 c. Clase de agregado. La arena y las cerniduras.** Resistencia y densidades relativas.

| | Compresión. | Resistencia transversal. | Densidades. |
|---|---|---|---|
| Arena y piedra..... | 100 | 100 | 100 |
| — y granzón..... | 94 | 89 | 102 |
| Cerniduras y piedra.. | 67 | 85 | 98 |

**79 d.** La mezcla graduada dió la **densidad**=1.14×densidad con la mezcla natural; para la igual resistencia, las mezclas graduadas necesitaron .88×el **cemento que se necesita** con las mezclas naturales.

(Esto significa un promedio de **economía** de un 25% **por m cúbico** del concreto, más ó menos. Allen Hazen, Sociedad americana de Ingenieros civiles, vol. 59, pág. 150, diciembre, '07.)

**79 e.** El exceso de arena fina ó mediana, ó la deficiencia de arena fina en el concreto menudo, disminuye la resistencia y la densidad.

**79 f. La resistencia y la densidad** son máximas cuando la mezcla llena exactamente los vacíos.

**79 g. Permeabilidad.** Véase la figura 10. « Poco se sabe sobre la acción del concreto para resistir el flujo del agua. » Pues entre « proporciones diferentes y diferentes tamaños de la misma clase de material, las leyes de la impermeabilidad son algo parecidas á las de la resistencia ».

Con un percentaje dado de cemento, las muestras **más densas** serán ordinariamente más impermeables. Cuando las densidades son iguales, las muestras **más ricas** serán las **más impermeables** (véase la figura). Las proporciones, sin embargo, son muy diferentes de las de la densidad ó de la resistencia; una pequeña diferencia en la composición, produce un gran efecto en la impermeabilidad. « **Diferentes clases de agregados** producen resultados muy diferentes en la impermeabilidad. » La figura demuestra el efecto de la **presión** sobre la **permeabilidad**.

**79 h.** El concreto con piedra del Parque Jerome y cerniduras dió proporciones mucho mayores de filtración en todas partes (máxima, 369 gramos por minuto) que el de arena de Cowe Bay y granzón. El concreto de piedra y arena dió, más ó menos, la mitad de las proporciones que se ven en la fig. 10.

**79 i.** La **permeabilidad** es algunas veces mayor con piedras **grandes** y otras veces con las **pequeñas**. Los resultados han sido especialmente erróneos con la piedra quebrada y cerniduras del estanque del Parque Jerome.

**79 j.** La « **permeabilidad** disminuye materialmente con la **edad** », aumentando mucho más rápidamente que lo que disminuye el **espesor del concreto**.

menor con arena y granzón que con piedra y cerniduras;
— — — — y arena;
— — piedra — y cerniduras.

— 80 —

**80. Richd. H. Gaines,** Junta del acueducto de Nueva York, S. A. de I. O., Trans., vol. 59, '07 diciembre, pág. 159.

**80 a. Permeabilidad y resistencia; arcilla y alumbre.**

**Muestras.** Mortero, 1 : 3, Portland, arena de Cowe Bay. Pruebas de tensión con probetas corrientes; pruebas de compresión y tensión con cubos de 5 cm. Edad de las muestras, de 20 á 30 días. Presiones, 2.80 á 5.60 kg/cm cuad.

**Resultados.** (1) Reemplazo del agua de la mezcla por una solución de **alumbre** de 2.5 á 5% (1 á 2% es suficiente). y dió una **impermeabilidad** casi completa.

(2) Reemplazo de 5 á 10% de la arena por **arcilla** molida fina; y (3) combinación (1) y (2) que dió aún mejores resultados.

Las muestras de arcilla (con alumbre y sin él) mostraron de 12 á 18% de ganancia en **resistencia** sobre las que no tenían arcilla.

El procedimiento se basa en **una teoría de la acción físicoquímica** entre los iones del electrólito (el alumbre) y las moléculas coloides (gelatinosas) de la arcilla.

Ninguno de los **procedimientos en uso hasta el presente,** que se han examinado, ha resultado conveniente para uso general.

**La cal apagada disminuye** ligeramente la **permeabilidad**; pero esta ventaja está más que compensada con la pérdida en **resistencia.** No hay razón química para que esto sea de otra manera.

— 81 —

**81. Profesor E. Morsch,** Zurich, para Wayss 'y Freitag A-G, Neustadt. « Der Eisenbetonbau », Stuttgart, Konrad, Wittwer, '08, citaremos las págs de esta obra.

**81 a. Relación de elasticidades,** págs. 27-32. **Muestras**; prismas cuadrados, largo medido, 35 centímetros. 1 parte de cemento Portland Manheim con 3 partes de una mezcla de arena del Rhin y granzón compuesta de 3 partes de arena, 0-5 mm; 2 partes de granzón, 5-20 mm. Agua, 14%. Cada esfuerzo se mantuvo durante 3 minutos. Algunas de las muestras se probaron en tensión; las otras en compresión.

*Compresión en millonésimas de la longitud primitiva.*

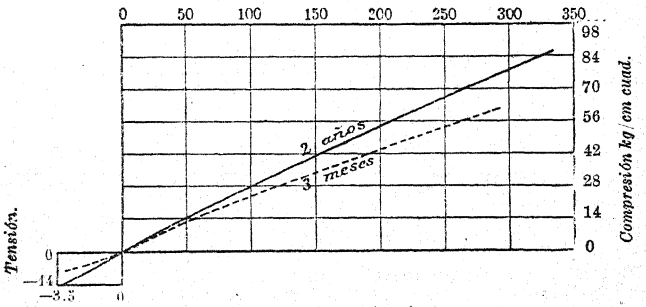

**Fig. 11.** Esfuerzo y estiramiento.

Los 2 años y los 3 meses de la línea continua y de puntos se refieren á la edad de las muestras.)

Resultados. **Las unidades de los esfuerzos y del estiramiento** como en la fig. 11. Las tensiones máximas, kg/cm cuad : 3 meses, 4.10; 2 años, 15.7.

**Coef de elasticidad, E.** Véase fig. 12.

**Con mezclas de 1 : 4,** para un esfuerzo dado en compresión, **E** fué en genera de 15 á 20% menos que con los de 1 : 3. En la tensión, **E** fué más igual en ambas mezclas.

**Con 8% de agua,** para una comp dada, **E** fué en general de 10 á 20% mayor que con 14% de agua.

**Para el índice**, véanse págs. 1346, etc.

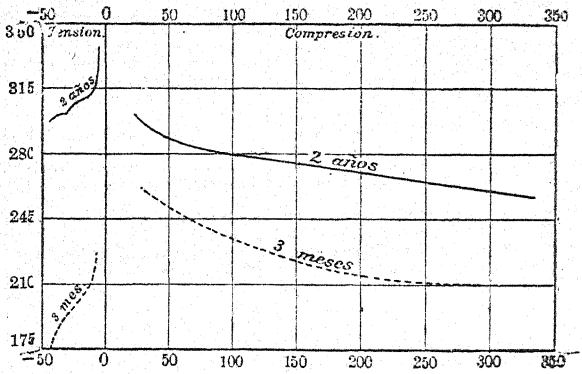

**Fig. 12.** Módulo ó coef de elasticidad.

(Los números verticales á la izquierda, de 175 á 350, dan en **miles** de kg/cm cuad los coeficientes E de elasticidad. Los meses y años de las curvas se refieren á la edad de las muestras.)

**81 b. Esfuerzo cortante.** Fig. 13. Las dimensiones en centímetros. Prismas de 18 cm en cuadro, 40 cm de largo. Mezcla de arena y granzón como en el ensayo 81 *a*.

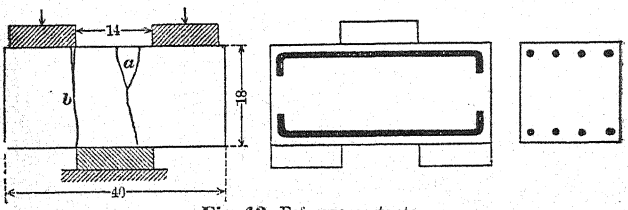

**Fig. 13.** Esfuerzo cortante.

**Sencillo.** La muestra se agrietó al principio, como la viga, en *a*. La presión se aumentó luego hasta aparecer la grieta del esfuerzo cortante, *b*.

| Mezcla. | Agua %. | Edad. | N.° de muestras. | Promedio del esfuerzo máximo cortante, kg/cm cuad *. | |
|---|---|---|---|---|---|
| | | | | Observado. | Calculado**. |
| 1 : 3 | 14 | 2.5 años. | 3 | 65.5 | 68.6 |
| 1 : 4 | 14 | 1.5 meses. | 3 | 37.1 | 38.5 |

* = 1/2 de la fuerza total aplicada ÷ el área de la superficie del esfuerzo cortante.
** Dada la resistencia á la tensión final, $t$, y la resistencia á la compresión final, $c$, de las piezas de prueba de la misma mezcla, edad y fórmula, el esfuerzo cortante = $V\!tc$.

**Armado.** Las barras (de 1 cm de diámetro) sirvieron solamente para mantener unidas las muestras, de manera de poder aumentar las presiones á voluntad. El concreto cedió primero al esfuerzo cortante.

| Mezcla. | Agua %. | Edad. | N.° de muestras. | Promedio del esfuerzo máximo cortante, kg/cm cuad. | |
|---|---|---|---|---|---|
| | | | | Concreto. | Acero. |
| 1 : 4 | 14 | 1.5 meses. | 2 | 36.5 | 3,248 |
| 1 : 4 | 14 | 1.5 — | 3 | 33.9 | 3,556 |

**81 c. Torsión**, pág. 45. Mezcla, 1 : 4. **4 cilindros sólidos**, de 79 á 98 días, de 26 cm de diámetro; largo sometido al experimento, 34 cm con cabezas hexagonales. M=el momento de torsión, R=radio del cilindro.

$t$ = al esfuerzo de torsión en las fibras extremas (véase pág. 528 *h* de este libro) $=2M/\pi R^3$.

$t$, en kg/cm cuad; máx, 19; media, 17; mín, 13.

**3 cilindros huecos**, como anteriormente, de 52 á 55 días; diámetro interior como de 15 cm, $r$=al radio interior.

$t=2MR/\pi\ (R^4-r^4)$,

$t$, en kg/cm cuad; máx, 94; media, 86; mín, 7.8.

**La unidad de resistencias mucho mayor de los cilindros sólidos** según las dan las fórmulas, se atribuye en parte á su mayor edad, pero especialmente al aumento en la unidad de presión de la circunferencia hacia dentro, debido á la cual el material más próximo al centro transmite más de lo que le corresponde del esfuerzo cort de torsión y alivia las partes exteriores.

**81 d. Adhesión**, pág. 49, figs. 14 y 15.

**Muestras.** Cubos de 20 cm. Mezcla, 1 : 4; 10 á15% de agua; edad, 4 semanas Barras redondas de 2 cm de diámetro, fig. 15, espiral de 10 cm de diámetro; alambre, .45 cm de diámetro.

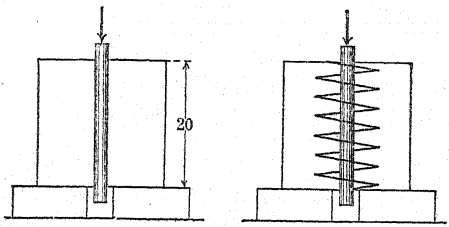

**Fig 14.**

Adhesión.

**82. Sandford E. Thomson.** A. S. T. M., Procs., '08, vol. 8, pág. 500.

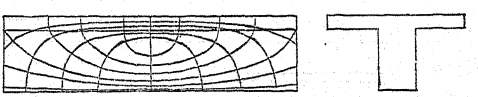

**Fig. 20.** Esfuerzos diagonales.

**82 a. Permeabilidad.** Efecto de la incorporación de la **cal apagada.**

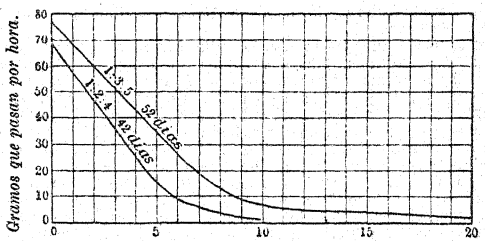
**Muestras.** Bloques cilíndricos, de 50 cm de diámetro, 40 de espesor; cemento Lehigh, arena buena mediana de rivera, roca de conglomeración parecida al basalto en su naturaleza; « una mezcla blanda esponjosa, como para usarla en la construcción ». Cal de Piñón de Rockland, Maine. La cal está expresada en % de peso de cemento seco. Las mezclas fueron como sigue :

| | | | |
|---|---|---|---|
| 1 : 2 : 4 | concreto con 0%, 4%, 7% y 10% cal; | 8% se prefiere; | |
| 1 : 2.5 : 4.5 | — con 0%, 6%, 10% y 14% | — 12% | — |
| 1 : 3 : 5 | — con 0%, 8%, 14% y 20% | — 16% | — |

**Tratamiento.** El agua bajo presión se introdujo al centro del bloque.

* Las dos cargas concentradas dividen la luz en tres partes iguales.

**Resultados**, 1 : 2 : 4 y 1 : 3 : 5, véase fig. 21. 1 : 2.5 : 4 dieron resultados intermedios entre los otros dos.



*Percentaje en peso del cemento, de cal hidratada.*

**Fig. 21.** Permeabilidad; Cal.

**82 b. La arena más ordinaria** requiere más cal, y viceversa.

**82 c. Si la presión va á ser aplicada dentro de un mes**, será mejor usar 10%, 15% y 20% respectivamente, en lugar de 8%, 12% y 16% como se recomienda en la Experiencia 82 *a*.

**82 d.** La pasta de cal ocupa como 2¼ veces el **volumen de la pasta** hecha con peso igual del cemento Portland, « y es por consiguiente muy eficaz para llenar las vacíos. El **costo de los trabajos grandes á prueba de agua** puede reducirse usando, con la cal, un concreto más fino del que sería necesario bajo otras condiciones.

— 83 —

**83. Richard L. Humphrey**, vigas de concreto sencillas, cubos y cilindros, resistencias de compresión y transversales y relaciones de elasticidad. « La resistencia de las vigas de concreto », U. S. G. S., Boletín n.° 344, '08. Pruebas para determinar el efecto, sobre **la resistencia transversal y de compresión**, de (1) **edad** de la muestra, (2) **consistencia** de la mezcla, (3) naturaleza del **agregado**.

**83 a. Muestras.** Vigas de concreto sin armar, cubos y cilindros. Cemento, una mezcla de 9 cementos Portland. Arena del río Meramec, « compuesta de granos de pedernal con superficies relativamente lisas ». « El análisis granulométrico demuestra que la arena resultó un poco más fina de lo que era de desearse ».

**Propiedades de la arena y del agregado usados.**

| | Densidad. | Vacíos, %. | Mallas por cm del cedazo. | | | | | Tamaño de mallas. | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | 80 | 40 | 20 | 12 | 4 | 6 mm. | 12 mm. | 19 mm. | 38 mm. |
| | | | Percentaje que pasó el cernidor ó cedazo. | | | | | | | | |
| Cenizas..... | 1.53 | 51 | 2.84 | 4.17 | 6.5 | 10.5 | 21.1 | 37 | 60 | 81 | 100 |
| Granito..... | 2.59 | 41 | 1.59 | 2.29 | 3.2 | 4.4 | 8.5 | 20 | 58 | 99 | 100 |
| Granzón..... | 2.45 | 33 | 0 | 0 | 0 | 0 | 1.0 | 43 | 79 | 95 | 100 |
| Piedra caliza.. | 2.49 | 37 | 2.96 | 3.48 | 4.2 | 5.2 | 10.7 | 29 | 61 | 96 | 100 |
| Arena..... | 2.60 | 38 | 0.20 | 1.30 | 13.9 | 64.0 | 97.0 | 100 | . | .. | .. |

**Proporciones.** 1 : 2 : 4 por volumen, excepto el concreto de ceniza que estuvo más cerca de 1 : 2 : 5. Todo el concreto se mezcló en un mezclador de mortero de impulsión de .75 m cúb. provisto de una tolva de tiro. Se mezcló 2 minutos seco, 3 minutos húmedo; después se apiló en un piso de cemento, se echó con palas en las carretillas y se llevó al piso de moldear. Cada lote suficiente para dos vigas,

**Para el índice**, véanse págs. 1345, etc.

de 20×27 cm y 3.66 m de luz, dos cubos de 15 cm y 2 cilindros de 20 cm de diámetro, 4.80 m de largo.

« **Mojado** »; liso y un poco viscoso inmediatamente antes de verterlo. Corrió hacia atrás del lado ascendente del mezclador sin tendencia á rajarse en su parte superior. Al echarlo no mostró porosidades ni piedras sueltas. Salpicaba al apisonarlo. Al terminarlo, el agua estaba de 6 á 12 mm sobre la superficie del molde.

« **Mediano** »; liso, pero con tendencia á formar terrones. Fluyó con menos suavidad que el « húmedo », una parte retirándose con suavidad, otra partiéndose en terrones. Al vaciarlo parecía terronudo, mostrando piedras, pero no vacíos. Las piedras estaban cubiertas por parejo con concreto. No se reunió el agua en la superficie del molde. La superficie se alisó fácilmente con la cuchara.

« **Húmedo** »; granulado. Poca tendencia á aterronarse. Se llevó á la parte superior del mezclador por el lado ascendente, cayó en piedras sueltas y fragmentos de mortero. Al vaciarlo mostró piedras y vacíos. Resistió al pisón. Se compactó con golpes de mano. No pudo alisarse con la cuchara.

**Concreto colocado** en moldes de acero aceitados, en 3 capas casi iguales y apisonado á mano. « Se tuvo gran cuidado en apisonar todos los concretos de la misma manera. »

**Tratamiento.** Todos los moldes se quitaron á las 24 horas, y las piezas se transportaron á un cuarto húmedo. Se regaron 3 veces diarias.

Las vigas se apoyaron, antes de la prueba, de manera que las sumas de los momentos y esfuerzos existentes entonces en el largo medido, se igualaran, de manera que todas las fibras en esa longitud tuvieran el mismo largo que si no estuvieran comprimidas, y las deformaciones, dentro de la distancia medida, se midieron de esta manera desde cero.

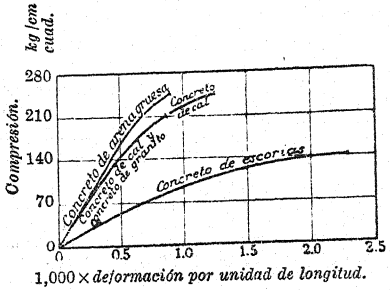


**Fig. 22.** Curvas de esfuerzos y deformaciones para diferentes agregados. Edad de las muestras, 26 semanas.

**Resistencia del concreto.**

**Resultados,** en general, término medio de 3 muestras.

| | Agua %. | Vigas. 20×28 cm y 3.66 m largo. | | | Compresión máx, kg/cm cuad. | | | |

(*Obs. del T.* Esta tabla, como todas las demás, la hemos convertido al sistema métrico. Para convertir lbs pulg cuad á kg/cm cuad, hemos multiplicado aquélla por .07, pues nos parece suficiente aproximación.)

— 84 —

**84. R. G. Clark,** Instituto de Ingeniería civil, Procs., vol. 171, '08, pág 11.5.

**84 a. El tiempo de fragua** se aumentó por la **aeración** y por el **aumento del agregado.** Un cemento puro que fragua en una hora, forma un concreto que requiere 4 ó 5 horas para fraguar.

— 85 —

**85. Hanisch y Spitzer,** Morsch, « Der Eisenbetonbau », '08, págs. 32-33.

**85 a. Módulo de ruptura,** $6M/bd^2$, **y resistencia de la tensión y compresión directas.**

**Muestras.**

Concreto, 1 : 3.5. Seis planchas de 268 días, de 60 cm de ancho, 7.8 á 11 cm de espesor; luz 150 cm.

**Tratamiento.** La plancha se quebró transversalmente; con los fragmentos se hicieron piezas para ensayos de compresión y tensión.

**Resultados. Esfuerzos** en kg/cm cuad.

| | Módulo de ruptura. | Compresión. | Tensión. |
|---|---|---|---|
| Máx..... | 54.5 | 351.5 | 29.0 |
| Mediana..... | 47.9 | 307.9 | 25.0 |
| Mín..... | 43.2 | 255.9 | 20.0 |

La comparación de los valores de la tensión con el módulo de ruptura demuestra

* $m$ = (espesor del eje neutro debajo de la parte superior de la viga) ÷ (espesor total de la viga).

† « Módulo de ruptura » = $6M/bd^2$, kg/cm cuad; M = momento bajo la carga máxima.

≑ El cilindro no se quebró.

**Para el índice**, véanse págs. 1346, etc.

que la **fórmula**, módulo de ruptura $=6M/bd^2$, no se aplica á los materiales en que, como en el concreto, el módulo de elasticidad varía mucho, y que los módulos de ruptura que se obtengan por esta fórmula deben usarse sólo como medios de comparación.

— 86 —

**86. Richard L. Humphrey y Wm. Jordán, Jr., U. S. G. S.**, Boletín n.º 331, '08. Resultados de los ensayos hechos en los Laboratorios para Experimentos con Materiales de Construcción, St. Louis, '05-7.

**86 a. Cerniduras de granzón.** Las resistencias á la compresión y tensión de los morteros parecen, en general, aumentar con la densidad de las cerniduras.

**86 b. Cerniduras de piedra.** En general, la resistencia de la mezcla fué mayor con las cerniduras de más uniformidad en la graduación. **La resistencia de la piedra** misma, de donde se obtienen las cerniduras, tiene una influencia importante en la resistencia del mortero resultante.

**86 c. La densidad** de los morteros es mayor con las arenas más densas.

**86 d. Morteros de arenas. Las resistencias** á la tensión, á la compresión y transversal fueron invariablemente mucho **mayores, con arenas densas** que con las que tenían grandes proporciones de vacíos.

**86 e.** La resistencia mayor se obtuvo cuando la arena estaba uniformemente graduada.

**86 f. Una « mezcla típica »** de 7 cementos Portland, con marca separada, llegó á la mayor **resistencia** á la tensión en 90 días. Como el mejor de ellos, mantuvo este máximo 180 días, y la pérdida subsiguiente, un año, y más tarde, no fué mayor que con el mejor de las marcas por separado.

**86 g. Edad de la probeta.** Los ensayos después de 180 días mostraron mayor uniformidad que á los 90 días, y períodos menores.

**86 h.** Después de ensayos á 180 y 360 días, las resistencias de todos los morteros de arena eran muy aproximadas una de otra, demostrando que la considerable variación de la **resistencia primitiva** no afecta seriamente la resistencia posterior.

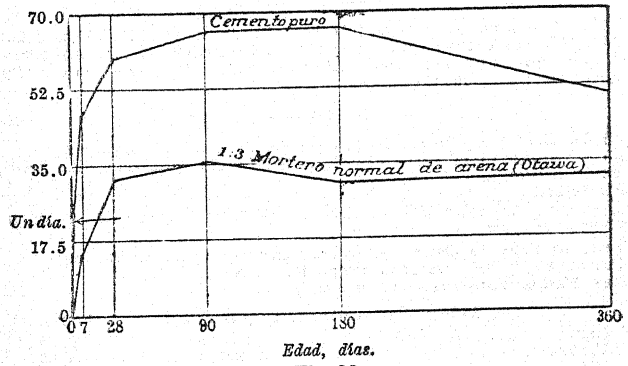

**Fig. 23.**

(*N. del T.* — Las cifras verticales de 0 á 70.0 son kgs/cm cuad, de tensión.)

**86 i. Resistencias á la tensión y compresión de los morteros de cemento Portland** puro y 1 : 3 arena superior de Otawa. Véanse figs. 23 y 24. Cada curva representa un promedio de 10 ensayos.

**Muestras.** El cemento era una mezcla de partes iguales de 7 marcas diferentes. Véanse Ensayos 86 *f*, 86 *g* y 86 *h*.

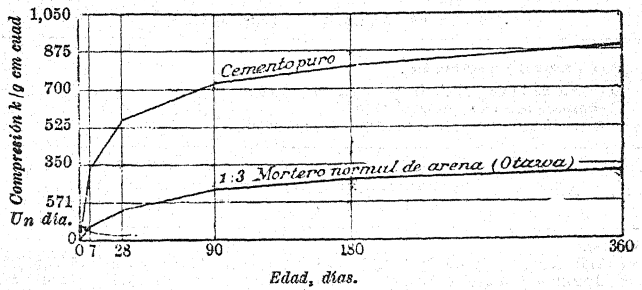

**Fig. 24.**

Las piezas para los ensayos en los moldes, se tuvieron en el gabinete húmedo 24 horas, después se conservaron en agua corriente, como á 21° C, hasta que se probaron. Probetas de tensión de 25 mm en cuadro. Ensayos de compresión, cubos de 5 cm.

**Resultados** como en las figs. 23 y 24.

**90 a. Agua de mar.** Charlestown, Mass. Arsenal.

**Arcos no armados**, construídos '01, por la Oficina de Depósitos y Muelles. **Agua salada de marea,** no muy sucia, pero **helada** á menudo, diferencia de marea 3 m. Especificaciones requeridas para la « construcción continua de muelle á muelle de los arcos ». Cara exterior del mortero de 7.5 cm, 1 : 1. Masa de concreto de 1 : 2 : 4, en 60 cm, detrás de la cara exterior, 1 : 3 : 6, al interior; « cemento superior y granzón local ». Probablemente poroso. No hubo esmero especial para la densidad ó impermeabilidad. Especificaciones que se indicaron : « El contratista debe presentar prueba satisfactoria de la durabilidad en el agua de mar de la marca de cemento que intenta suministrar. » Las enjutas que están á la vista se construyeron después de terminados los arcos. Seco, bien pisado. Desintegración grande. El daño principalmente entre alta y baja marea. El concreto de la parte posterior sufrió considerablemente.

— 91 —

**91. U. James Nichols.** Melbourne, Victoria, E. W., '08, dic. 24, pág. 710

**91 a. Electrolisis** en los morteros de cemento.

**Muestras.** 16 cilindros de 20 cm de diámetro y 20 cm de altura. Cemento Portland superior, arena gruesa con 51% de vacíos. El mortero se apisonó por capas

de 4 cm, hasta que un poco de agua fluyó á la superficie. El electrodo positivo normal á un tubo de acero de 2.5 cm diám y 30 cm largo con el extremo inferior tapado con un corcho, y sumergido, en el eje del cilindro, á una profundidad de 12 cm en el concreto.

**Tratamiento.** Los cilindros se colocaron en agua dulce por más de 28 días. Se probaron 8 cilindros con **corriente constante** de .1 de amperio; 5 con tensión **constante** como de 115 voltios (corrientes altas, uno con corriente inversa), 3 no se sometieron á corriente. Para la corriente, los cilindros se colocaron en una solución de sal de 3% en baldes de metal separados (que normalmente formaban los electros negativos), y montados en serie. Los cilindros tenían de 29 á 57 días de edad al principio de la prueba.

**Resultados.**

**Todos los cilindros** sometidos á la corriente se **agrietaron.** Las grietas se atribuyeron á la acumulación y presión de los gases que se formaron. Al principio las grietas eran de forma capilar y exudaban humedad, humedeciendo la superficie adyacente. Las grietas se ancharon bajo la corriente continua. Bajo la corriente constante las grietas aparecieron al llegar la resistencia al máximo. La resistencia, en general, fué inversamente proporcional **al percentaje de arena.** Los cilindros n.os 1 y 2 se abrieron fácilmente al forzarlos. En los n.os 2 y 9 **el tubo de acero se enmoheció,** y se formaron concavidades en el exterior, adyacentes á las grietas. Con corriente inversa (de potencial constante) (el n.° 12) no se enmoheció ó agujereó.

**Los cilindros que no se sometieron á la corriente** no se agrietaron. Necesitaron como veinte golpes con un martillo pesado y un cincel fino para quebrarlos. No hubo moho.

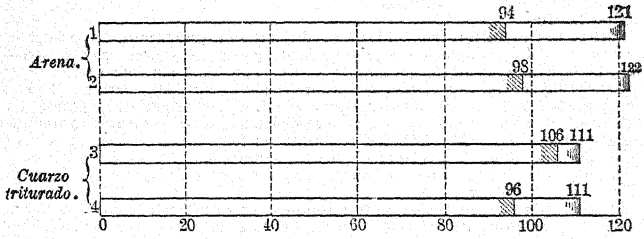
**94 a. Densidad de la arena, forma del grano.** 100 medidas de granos de arena redondeados, ó de granos de cuarzo triturado que se vertieron muy despacio en 60 medidas de agua. Los ensayos 1 y 2 se hicieron con granos de arena, los n.os 3 y 4 con granos de cuarzo triturado. El lado izquierdo de cada diagrama, fig. 25, representa el fondo del envase; y los números, 94, 121, etc., muestran las elevaciones de la superficie de la arena y del agua respectivamente, después de verter los granos de arena en el agua.



*Elevación de las superficies de la arena y del agua sobre el fondo del depósito.*

**Fig. 25.**

En el n.º 4, el cuarzo triturado se removió en el agua, de vez en cuando, mientras se introducía, para desalojar el aire, que, á pesar de lo despacio de la introducción, los granos de arena hubieran arrastrado en el agua. El hecho de que el agua llega á la misma altura en 4 que en 3, indica que no arrastró más aire en 3 que en 4 y que el movimiento puso los granos en mayor contacto que cuando se dejaron quietos.

# RESUMEN DE LAS ESPECIFICACIONES, ETC.

## PARA LOS TRABAJOS DE CONCRETO EN GENERAL

Páginas 1403 á 1420.

## LISTA DE LAS ESPECIFICACIONES, ETC., QUE SE USAN

### Lista alfabética.

Véase la Lista clasificada, pág 1402.

**AH**, Puerto de Algoma, Wisconsin, Tajamar de cajones, etc., Ing. de los E. U., '08, enero 24.

**BB**, Tajamar, Búffalo, N. Y., Emile Low, Ing. de los E. U., A. S. C. E., Trans., '04 junio, vol. 52, pág. 73.

**BR**, Puerto y Canal de Black Rock, Búffalo, N. Y., Muros de Esclusa, Ing. de los E. U., '07, dic. 19.

**Bu**, Burlington, Vermont, Planta de Filtro Mecánico, Hering y Fuller, '07.

**Ch**, Chicago, '08; enmiendas propuestas al Código de Construcción de '05-6.

**Ci**, Cincinnati, O., Geo. H. Benzenberg;
**a**, Filtros, etc., '05; **b**, Depósito Principal, etc., '06.

**Para lista** de especificaciones para concreto, véase págs 1401-02.

Para comparar de una manera comprensible los requisitos de las diferentes Especificaciones, se debe tomar en cuenta la naturaleza del trabajo á que se refieren.

## RESUMEN

### Cemento.

**1. Marca.** Portland ó natural, **NY**; el Portland debajo del quicio, el natural en todas las otras partes del cimiento, Portland en las paredes de trabazón, pero no como respaldo, 60 cm de espesor en la base, Portland y natural ligados, **IM**; para cemento armado Portland, **G**; Portland americano, **CS, BR, Hb, FW**; cemento Portland « Universal », **SE**; cemento hecho por manufactureros de reputación establecida (trabajando con éxito no menos de dos años, **F**), marca de éxito continuo (en América, **F**) durante los últimos 5 años (3 años, **CS**) **G**; en uso satisfactorio en cantidades semejantes por el Departamento de Ing. de los E. U., **TR**; de uniformidad probada, en uso, no menos de 3 años, en un clima parecido, **CR, Hb**, se debe usar solamente una marca, **G**; excepto cuando haya razón para lo contrario, **F**; sólo una marca en los monolitos, **FP**. El Portland en cemento armado y donde esté sometido á choque ó vibraciones ó presiones que no sean la compresión directa, el natural en el trabajo macizo en que el peso es de más importancia que la resistencia, y cuando la economía es el factor que rige; el puzolano solamente en la parte subterránea de los cimientos, no expuesto al aire ó al agua corriente, **JC**.

**2. Requisitos. Para resistencias**, etc., véase Resumen de las Especificaciones para el cemento, por la A. S. T. M., pág. 940, Informe de la Junta de Ingenieros de los E. U., Estudios Profesionales, n.º 28, Cuerpo de Ing. de los E. U., '019 37, y Resumen de las Especificaciones por las Comisiones de Ingeniería Mod to de la Gran Bretaña, pág. 940. **Para las pruebas**, véase el Resumen de la A. S. C. E., pág. 942. Fragua lenta, **FP**; ha debido probarse por más de 6 meses, más de la meses antes de la publicación del permiso, **L**; debe llenar los requisitos de los Estudios Profesionales n.º 28, Cuerpo de Ing. de los E. U., '01, pág. 940, **BR, AH, TR, CR, FW, Wv, FP, Hb.**

**3. Embarque.** Los « bultos deben contener 380 lbs (172 kg) ó algún divisor par de 172 kg », **Lv**; en barriles ó sacos de tela, **NO**; saco, 42 kg, neto, un barril=4 sacos, **NO**; en barriles, forrados con papel, **CR, WH**; en sacos de tela, **Ci**; puede entregarse en sacos de papel, **Wv.**

**4. Almacenaje** en la obra. En edificio ó prueba de intemperie con el piso levantado sobre el suelo ($<$ 15 cm, **T y T**) 2 semanas bajo condiciones análogas á las del trabajo, **Ci**; el cemento en sacos puede usarse después de 3 meses de almacenaje, recháceselo si se pone terronudo ó si se daña de cualquier otra manera dentro de ese tiempo, **BR**; el cemento que se conserva hasta después del invierno se vuelve á probar antes de usarlo, **Wv.**

### Arena.

**5. General.** Sílica, dura, limpia, aguda, **G**. Medianamente limpia, ordinaria, **F**; gastada por el agua, vacíos=35%, **SE**. La « agudeza » omitida intencionalmente, **T y T**. Arena de río, **Ci, a**.

**6. Tamaño.** Bien graduado con granos finos, medianos y gruesos, **F, Lv, NO, CO**. Gruesa, ó fina y gruesa, mezcladas, **CS, T y T**. Predominando la gruesa; prefiriendo la gruesa á doble ó triple costo, **T y T**. Mediana, **Ci, a**. La más grande que pase por un cernidor de 6 mm, **G**. $>$ 10% más gruesa de 3 mm, **NO**; $<$ 50% retenida en el cedazo n.º 30 (agujeros de 14 mm cuad), **WH**. $>$ 40% que pasó cedazo n.º 50 (400 mallas por cm cuad), **Hb**. $>$ 3% muy fina, **NO, Co, Ci, a**. $>$ 5% muy fina, **Bu**.

**Materia extraña** (arcilla, marga, palos). Ninguna, **CS, T y T**; $>$ 2% **NO**, $>$ 3 %, **Co, Lv**; $>$ 5%, **Wv, OD, TR, CR, Bu**, $>$ 10% arcillosa **AH**. $>$ 3% arcilla, etc., $>$ 2% mica, **FW**; $>$ 4% de marga libre, **Hb**; la arena puede estar húmeda, no mojada, **TR**; almacenada en una plataforma de madera, **CR**, ó en almacén, **Wv.**

**7. Cerniduras.** El polvo de piedra triturada, que pase por un cernidor de 6 mm, puede sustituir parte de la arena ó toda ella, **T y T**; « las cerniduras y piedras

trituradas pueden sustituirse por arena y granzón, en condiciones especiales », **F**; se permiten las cerniduras, **BR, CR**; si pasan el cernidor de 6 mm, **TR**; se prefieren las cerniduras á la arena, **AH.**

### Agregado (« Balasto »).

**8. Clase.** Polvo de arena, granzón ó piedra quebrada, **BB**; granzón ó piedra quebrada, **G**; ó ambos, **BR**; granzón, **Lv**; (véase Cerniduras); granzón lavado por el mar, **Lp**; guijarros de piedra volcánica gastados por el agua, **SE**; piedra limpia, granzón, ladrillos duros quebrados, terra cotta, escoria de hornalla ó cenizas duras limpias, **Un**; se prefirió la piedra quebrada, se permitió el granzón en el interior de los muelles, pedestales y empotramientos, **WH**; piedra quebrada, **AH.**

**9. Requisitos.** Limpio, duro, durable; libre de polvo, de marga, arcilla y materia descomponible; lavado ó cernido si fuese necesario, **G**; próximamente cúbico, **CS, AH**; libre de pedazos largos delgados, **BR, NO, CS**; $<$ 2,000 kg /m cúb, **FP**; $<$ 2,080 kg, **Hb**; vacíos=31%, **SE**; empapado antes de usarlo, **G**; pero que no contenga agua, **Wv**; consérvese bien regado, **IM, Hb.**

**10. Tamaños :** mín, 6 mm, **G**; 3 mm, **FW, Mc**; máx, 19 mm, **Un**; 38 mm, **Bu**; 50 mm, **G**; 63 mm, **Hb**; 75 mm, **NO, Co, Ci, a, FP, SE**; granzón, 75 mm, **F**; piedra, como sale del triturador, **F, Mc, AH**; 25 á 63 mm, de acuerdo con la clase de la obra, **AH**; para los cimientos, 50 mm; para la superstructura, 40 mm; para vigas y columnas, 25 mm, **L**; granzón, $<$ 90% sobre 40 mm, $>$ 10% de arena, **Hb.**

| | Granzón ó arena contenidos en un m cúb de piedra. | | | | | |
|---|---|---|---|---|---|---|
| Agregado. | m cúb. | kg. | | m cúb. | kg. | m cúb. kg. |
| Piedra;... gruesa, | .63 | 861; | fina, | .33 | 486; | polvo, .11 176 |
| Granzón;. guijarros, 3 mm. | .80 | 1,304; | arena, | .29 | 469; | ... ... |
| Arena;... granzón, 3 á 6 mm. | .47 | 755; | arena, | .59 | 949; | ... ... |

**11. Almacenaje.** Almacenado en plataformas de madera, **CR, Wv;** ó en arcones de madera, **Wv.**

**12. Concreto de ceniza.** Se permite sólo para pisos, techos y rellenos, **Ms.** Concreto de ceniza armado se usa solamente con el permiso del inspector de edificios, **L.**

**13.** « Se puede usar en todo edificio en que la construcción á prueba de fuego es obligatoria, ó cuando se use en construcciones ordinarias, ó que arda despacio », pero no en columnas, muelles ó muros. Cenizas de caldera de vapor completamente quemada, limpia; mezcladas con cemento Portland á no menos de 1 : 7. Las cenizas deben pasar la malla de 25 mm en cuadro, **Ch.**

**14.** « Todos los otros requisitos especiales y sistemas de cálculo para el concreto armado como se requieren en este capítulo modifican y reglamentan el uso del concreto de ceniza en los edificios », **Ch.**

**15. Piedras grandes.**

Duras, enteras, durables, tan grandes como se puedan manejar con comodidad, bien lavadas, colocadas mojadas; una dimensión $<$ 30 cm, ninguna dimensión menor de 10 cm; ninguna de las piedras á menos de 5 cm de las superficies expuestas en el enlucido. El concreto se comprime en su lugar con pisones livianos, **Co.**

**16.** $>$ 46 kg, $<$ 75 mm distante de las armaduras ó de otras piedras grandes. (De las especificaciones para el Asilo de soldados.)

**17.** Se permite en los muros $>$ 45 cm de espesor, diámetro $>$ un cuarto del espesor de la pared, el volumen de la piedra $>$ que un quinto del volumen de la pared, **Yo.**

**18.** Piedras que pueda un hombre cargarlas y más grandes, más ó menos cúbicas; los pedazos largos y chatos se deben rechazar ó quebrarse; las piedras se distribuyeron con alguna uniformidad en toda la obra; $<$ 20 cm de separación, $<$ 60 cm del tope ó cara hacia la corriente; se dejan caer separadamente en el lecho de concreto húmedo, apisonadas si fuese necesario; se acuña con pala alrededor de las piedras y debajo de ellas el concreto; cada piedra se cubre con concreto antes de colocar las otras. Usense tantas piedras como sea posible sin faltar á estas condiciones, **Mc.**

**Para lista** de especificaciones para concreto, véanse págs. 1401-02.

**19.** « Peñas ». Piedras desde una carga de hombre hasta de varias toneladas (algunas veces de mampostería vieja), que forman como el 30% de toda la obra < 30 cm de la superficie del muro. Se colocaron en la capa superior de concreto de manera de formar trabazón con la capa siguiente prolongándose dentro de ella, **Lp.**

**20. Proporciones.** Véanse págs. 1297 á 1301.

### Medidas de los ingredientes.

**21.** El cemento se mide « como si estuviera compactado de manera que, 172 kg de cemento Portland seco tangan un volumen de .108 m cúb », **Lv**; el cemento se mide flojo, **CS, WH**; 1 saco de cemento < 42 kg=.028 m cúbico, **NO, Ci.** El cemento se mide como viene embalado por el fabricante, **OD, L, T y T.** La arena y el agregado se miden echándolos flojos en la caja de medir, **G.** Todo se mide flojo, **CS, WH**; 46 kg de cemento se suponen que miden .028 m cúb, **F.**

### Consistencia.

**22** En general, « muy húmedo », **NO**; agua como para que suba á la superficie por compresión moderada, **CS**; sin gran trepidación, **OD, TR**; suficientemente fluido que no necesite pisón, **Mc**: poco ó ningún pisón, **Hb.**

**23.** (**a**) Para masas ordinarias de concreto, como cimientos, muros fuertes, arcos grandes, pilas y estribos, mezcla **mediana** de una consistencia tenaz gelatinosa, que trepide al pisarla, **T y T.**

(**b**) **Para el concreto de ripios y para el concreto armado,** como muros delgados de edificios, columnas, puertas, conductos, estanques; **muy húmedo ó pastoso**, tan blando que hay que andar ligero para evitar que se derrame en la pala, **T y T.**

(**c**) **En lugares secos para masas de cimientos**, que deben soportar gran compresión dentro de un mes después de su colocación, úsese « el concreto » **seco** », con consistencia de tierra húmeda, con tal que se extienda en capas de 15 cm comprimiéndolas hasta que el agua brote á la superficie. No se permite en el con creto armado, **T y T.**

**24.** « **Aguado** ». Los trabajadores al extender el concreto en su posición final, usan botas de cuero á prueba de agua y se meten hasta el tobillo en el concreto, **Lp.**

**25. En los cimientos**, « suficiente agua para que haya cohesión al apisonarlos, con pisones de 14 kg forrados de hierro »; en **los muros de esclusas,** bastante para la completa hidratación del cemento; bastante para que haya coherencia después de mezclado completamente; más plástico que arena húmeda; el apisonado completo debe traer el agua á la superficie; la trepidación incipiente marca el límite; un exceso de agua en una carga puede corregirse en la próxima; consistencia variada; de vez en cuando, para llenar las condiciones de temperatura **IM.**

**26.** El concreto para subestructuras mucho más seco que para la superstructura, **SE.** El concreto que se va á colocar debajo del agua debe estar medio seco, **Ph.**

**27.** Agua por carga, aproximadamente :

3.5 m cúbicos por lote de 43.2 m cúbicos, reducidos á 28.5 m cúbicos al apisonarlo;

2.5 m cúbicos por lote de 28.8 m cúbicos, reducidos á 20.0 m cúbicos al apisonarlo, **BB.**

### Mezcla.

**28.** A mano para los cimientos, con mezcladores cúbicos para los muros de esclusa, **IM**; con mezclador cúbico, **SE**; en máquina, **F, BR, AH, NO, Bu, Co, Ci, b**; á máquina cuando la cantidad de la obra pase de 1,000 m cúbicos, **CS**; por máquina en general, **TR, Hb, WH**; « con preferencia por los mezcladores del tipo continuo que miden automáticamente y vierten las proporciones justas en pequeñas corrientes dentro de la cámara de mezclar », **F**; por máquina de lote fijo, **Bu, Ci, b**; « por mezclador mecánico de lote fijo. excepto cuando se necesitan cantidades pequeñas ó cuando la condición del trabajo hace que la mezcla á mano se prefiera; mezcla á mano... solamente cuando la aprueba la Oficina de Inspección de Edificios », **Ph**; mezclador de lote fijo, **Hb, CR, W'v,**

**FW**; $<$ 100 m cúbicos por día de 8 horas, **FW**; se prefieren los mezcladores de lote fijo, los mezcladores continuos solamente con permiso escrito del ingeniero, **WH**.

**Método**. Los materiales se mezclaron secos antes de añadirles el agua, **CS**, **NY**; se remueven $<$ 100 veces, **Ci**, **b**. « En toda mezcla se medirá el material para cada lote »; el agregado, si está caliente y seco, se humedecerá antes de ir al mezclador, **Ph**. Un lote se descarga completamente antes de introducir el otro. No menos de 25 revoluciones por cada lote, removiendo el concreto no menos de una vez en cada revolución, **Un**; orden de la carga : 1.º el granzón, 2.º el cemento, 3.º la piedra, 4.º el agua, cada carga se hace girar $<$ 2 minutos, $>$ 9 revoluciones por minuto, se le darán revoluciones adicionales cuando el tiempo lo permita, **IM**.

**29. Mezcla del lote.** Cemento (60 lit por lote) mezclado en una pasta gruesa en la plataforma. Primero guijarros, después arena y pasta de cemento, después piedra quebrada, vaciada, por el agujero de la plataforma, en la caja que está debajo en el carro. La caja se vacía en el mezclador; 5 á 10 revoluciones, de 7 á 14 lotes por hora. Se necesitan 12 hombres para apisonar 14 lotes, **BB**; primero arena, después cemento, después agregado, después agua, **TR**, **OD**.

**30. Mezcla á mano**. El cemento y la arena se mezclan secos; se añade piedra mojada; se añade agua, **CS**. El cemento y la arena se mezclan secos, se añade agua, el agregado se extiende en un espesor de no más de 5 cm, se riega, se extiende mortero sobre el agregado y se mezcla, **Ph**. El cemento y la arena se mezclan secos, se añade agua, se le mezcla mortero, se le añade agregado (mojado), se mezcla todo, **Hb**; la mezcla de arena y agregado se extiende primero en una capa delgada sobre una plataforma de madera, se le extiende cemento encima, se mezcla seca, se revuelve al ir añadiendo el agua; la piedra quebrada, si se usa con granzón, se añade húmeda á la masa húmeda, **WH**.

**31**. Sobre una plataforma sin rendijas, bastante grande para dos cargas de no más de 1 m cúbico cada una. El cemento y la arena se extienden en capas delgadas y se mezclan secas hasta que tengan un color uniforme.

Después úsese uno de los 3 sistemas, como sigue :

(1) Mezcla de cemento y arena extendida sobre la capa de piedra;

(2) La piedra se echa con pala sobre la mezcla de cemento y arena. En (1) ó (2) revuélvase 3 veces, añadiendo agua en la primera revolución;

(3) El mortero hecho con la mezcla del cemento y la arena se extiende sobre la piedra. La masa de mortero y piedra se revuelve dos veces, **T y T**.

**32**. En todos los casos, el resultado debe ser un concreto suelto de color y apariencia uniformes, con las piedras penetrando completamente en el mortero. La consistencia debe ser uniforme en todo él, **T y T**.

**33**. « A medida que se llenaba la caja del granzón, se le agregaba el cemento gradualmente, de manera que, cuando aquélla estaba llena, la del cemento estaba vacía. Se quitó la caja entonces, y se niveló el montón, dándole un espesor uniforme de $>$ 30 cm, y se mezcló luego echándola hacia atrás y hacia adelante dos veces », se añadió el agua al final de la segunda removida, **Lp**.

## Armaduras (tapialeras *).

**34. Forro**. De tablas bien sazonadas, de 5 cm de espesor, todas acepilladas, con lenguetas y ranuras para trabarlas, **Co**, **b**; 5 × 15 cm de pino, acepilladas en todos los lados, **Hb**; las tablas acepilladas en un lado y dos cantos; un canto ligeramente biselado y colocado contra el canto cuadrado de la plancha siguiente, **Yó**; tablas de pino con preferencia de 5 × 15 cm, acepilladas y machihembradas, **WH**; las formas para las faces descubiertas, con lenguetas y ranuras ó biseladas; las armaduras para muros deben reforzarse y, si es posible, que tengan los lados unidos con alambres, **Ci**; las juntas de los extremos cuadradas y reforzadas con postes, **Hb**; las juntas que queden abiertas se llenarán con arcilla dura inmediatamente antes de colocar el concreto, **Hb**.

Si las **tablas usadas** no están maltratadas, pueden usarse otra vez; pero para trabajo visible deben limpiarse y aceitarse, **Hb**.

**Postes**. Generalmente de 7.5 × 20 cm de pino, acepillados en ambos cantos del mismo alto de la pared, $>$ 1.20 m de distancia, **Hb**.

Las cimbras y las armaduras se deben humedecer, **IM**; si fuese necesario, antes

---

* (*N. del T.* — Así las llaman en España cuando se usan en los muros).

**Para lista** de especificaciones para concreto, véanse págs. 1401-02.

de colocarlas, **NO, Ci, b**; ó aceitarlas, **NO**. De acuerdo con las circunstancias, deben mojarse las armaduras (excepto en temperaturas de congelación) ó engrasarlas con aceite crudo antes de colocar el concreto, **T y T**; aceitadas inmediatamente antes de usarlas, **Hb**; pintadas ó aceitadas antes de volverlas á usar, **CR**; humedecidas inmediatamente antes de poner el concreto, conservándolas húmedas hasta que el trabajo se haya endurecido, **TR, Wv**.

Para la quitada de las armaduras, véase p. 1250.

**35.** En el lado del muro que da contra la corriente en un dique, las armaduras deben ser sólo lo suficientemente lisas para que trabajen bien, y no deben tener huecos. En el borde del vertedero y la cara del muro que da hacia la corriente, las armaduras deben tener las superficies acepilladas de manera que el trabajo quede liso al terminarlo, **Mc**.

**36.** Las agujas ó varillas de ligazón que se dejen en el concreto no deben llegar más cerca de 5 cm de la superficie del concreto, **CR**; los extremos salientes de los pernos y varillas de hierro deben cortarse y taparse con concreto, **BR, AH**; no cincelados, sino aserrados ó quitarlos de cualquier otra manera sin sacudir la obra, **AH**; los postes para sujetar las armaduras no se deben insertar á más de 1.20 m de la parte superior de las paredes, **BR**; no deben aparecer pernos, etc., en la obra terminada, **OD**.

## Colocación, removida y apisonado.

**37. El trabajo nocturno** se prohibe en general, **TR. Tiempo de colocación**; el concreto debe colocarse dentro de 30 minutos después de mezclado, **AH, NO, Ci, b**; $>$ 30 minutos « entre la mojada del cemento y la colocación final del concreto en el lugar », **F**; antes de la fragua inicial, **TR, OD, CR, Wv, FW, Hb, Bu**; después de la mezcla, la masa se mantiene en movimiento hasta colocarla en un vehículo para el transporte, **TR**. No se permite **retemplada** ó nueva manipulación, **TR, CR, NO, Bu, Co, Ci, b, JC**. El concreto en que se hayan separado los materiales, debe volverse á mezclar (á mano, **BR, AH**); antes de colocarlo, **T y T**.

**Manipulación.** En el concreto muy mojado, se deberá extraer el aire, removiéndolo, empujando las piedras hacia adentro, y removiendo el concreto **debajo de las barras**, etc., **G**; por medio de barras de acero ó hierro, como de 10×15 cm con mangos largos ajustables, de modo que los trabajadores no tengan que pararse en el concreto, **NO, Ci, b**. El concreto debe removerse ó acomodarlo en su lugar con un apisonado suave, **Bu, Co**; apisónese hasta que el mortero salga á la superficie, **AH, BR**; hasta que todos los vacíos estén llenos y el agua fluya á la superficie, **CS**; un apisonador no debe hacer más de dos m cúbicos por hora, **BR**; el pisón debe tener una superficie de golpeo no menor de 200 cm cuad, que no pese más de 5 kg, **Co**; faz 15 cm en cuadro, peso, con el mango, como 9 kg, **CR**; pisones de 14 kg con aro de hierro, área de la faz no más de 30 ", **IM**; pisones de 18 kg, **SE**; el concreto se coloca sin pisarlo, **FP**.

**38. El concreto seco se humedeció**, regándolo, pero no con chorros, **CR**.

**39.** El concreto se debe remover continuamente **alrededor de la armazón** con hierros aparentes, á medida que se coloca. Se prohibe la llenada completa de las armaduras y el empozamiento consiguiente. El concreto parcialmente en fragua no debe sufrir choques, **Ch**.

**40. Colocación en capas.** Se debe tener cuidado de quitar toda la espuma, que salga en el concreto, antes de colocar la próxima capa, **Lp, JC**.

**41.** Se prohibe que el concreto se descargue directamente de la caja ó carro, ó se eche con palas en su lugar, así como el uso de canales, **OD, Wv, FP, TR, CR**; no se debe dejar caer de más de 1.80 m, **FP**; 1 m, **Wv**.

**42.** No se debe **caminar** en la parte terminada hasta que frague, **OD, Co**.

**43. Espesor de las capas.** No más de 15 cm, **Wv, BR, OD**; como 15, **CR**; como 15 después de pisadas, **TR**; 15 á 20, **CS**; $>$ 15, **F**; $>$ 10 cm, **SE**; con mezcla seca en los declives $>$ 10, **F**; $>$ 10 en los cimientos, como 15 en las paredes de atrás, **JM**; $>$ 22, **Hb**; $>$ 30, **WH**; de manera que cada capa pueda incorporarse á la anterior, **T y T**.

**44.** No se permitieron capas, **Bu, Co**; las capas no deben concluir por una orilla delgada, **FP**; cada capa completa (apisonada, **CR**) antes de colocar la

siguiente, **FP, CR**; cada capa de un día de trabajo se coloca antes que fragüe la capa de abajo, **TR**.

**45. En cimiento de roca viva.** La roca se limpia y lava con escobas de alambre, se hace escabrosa si fuese necesario, se cubre con una capa espesa de una mezcla de cemento puro, **CR**; se hace un lecho de mortero húmedo, **FW**; de 12 mm de espesor, **TR**; el concreto se ancla á la roca con barras de acero, si fuere preciso, **CR**.

## Juntas.

**46. Modos de evitar las juntas horizontales.** Los muros, etc., se construyen en secciones alternadas, tan cortas que puedan quedar monolíticas; estas secciones se traban por juntas verticales que se alternen, **G**. Las juntas continuas desde el cimiento hasta la parte de arriba, **CR**; « las juntas se deben formar entre las secciones contiguas de concreto á 1.20 m hacia abajo, desde la superficie, por una capa de papel alquitranado », **BR**; el machihembrado debe tener una capa delgada de mortero, de 1 : 5, ó más débil, que se pone antes que se coloque el concreto contra ella, **Hb**.

**47. Juntas entre el trabajo viejo y el nuevo.** Las superficies descubiertas se cubren y se conservan húmedas hasta continuar el trabajo, **CR**; los filos astillados ó quebrados, se deben rebajar, **CR**; la superficie vieja se debe dejar escalonada para formar trabazones, limpiándola y mojándola antes de añadir el trabajo nuevo, **FW, G**; se limpia con cepillo de alambres tiesos y vapor de agua, **FP, BR, Hb**; si fuese preciso, **F, Lv**; se le hace una sup áspera con un pico, si fuese preciso, **BR**; listones de madera, de 10 á 15 cm de ancho, con los lados en bisel, que se incrustan $\lessdot$ 7 cm, quitándolos antes que el concreto se endurezca completamente, **NO**; entre el trabajo viejo y el nuevo un lecho de mortero de 1 : 3 de 2.5 cm de espesor, **NO, Co**; capa de mortero de 12 mm, **FP**; la superficie vieja se cubre con un sedimento de cemento puro con consistencia de melado, **BR**; ó cemento seco, **OD**; cemento seco esparcido con un cepillo, **Hb**; con una capa de mortero, **TR, FW**; la superficie vieja, restregada con mortero de 1 : 2. **CS**; con pasta gruesa de cemento puro introducido en la superficie con escobas **CR**; calzado como se ha indicado, **FW**.

**48.** En las juntas horizontales de muros delgados, ó en muros que deben soportar **presión de agua**, ó en otros lugares importantes se puede necesitar junta de mortero. Los estanques, etc., con muros delgados que deben contener agua, se deben fabricar como monolitos, continuando el trabajo, si fuese necesario, de día y de noche, **T y T**.

**49. Cuando se suspende el trabajo** por más de una hora, se deben nivelar los bordes exteriores de la última capa, dejando la parte central de la superficie 15 cm más baja que los bordes, **CR**.

**50.** Unión entre el concreto nuevo y un muro viejo. Cavidades para machihembrado, 60 cm de ancho en la cara, 80 cm atrás, 40 cm de profundidad, se cortan verticalmente en la mampostería, á 1.20 m de separación, **Lp**.

**51.** La última capa que se coloque se dejará tan áspera como sea posible, de manera que sobresalgan las piedras incrustadas. La superficie se limpiará, lavará y se rociará con cemento puro, **Mc**.

## Colocación debajo del agua.

**52. Debajo del agua.** No debe colocarse concreto debajo del agua (sin permiso explícito, **F**; excepto para tapar filtraciones y manantiales, **TR**); no se debe permitir que el agua llegue sobre una obra nueva hasta que esté enteramente fraguado, **IM, Wv, TR, OD**; no menos de 24 horas después de fraguado, **Lv, NO, Co, Ci, b**; si se coloca en el agua antes de fraguar, la mezcla deberá ser 1 : 2 : 3, **WH**; 80% del trabajo debe construirse bajo el nivel del agua (dulce), **SE**; el concreto para colocarlo en el agua debe estar medio seco, **Ph**; los sacos se deben bajar hasta unos pocos cm de la superficie en que se va á depositar el concreto, **FW**.

**53.** Cuando las armaduras llegan debajo de la baja marea se taparán las filtraciones debajo de aquéllas, para impedir las socavaciones antes de la fragua; para esto, se colocan sacos, llenos de arena, ó lona de jute, debajo del concreto á 30 cm, clavada á lo largo de la parte inferior de la armadura, por el lado dentro, **FW**.

**Para lista** de especificaciones para concreto, véanse págs. 1401-02.

### Lluvia.

**54. Lluvia.** Durante la lluvia no se debe hacer trabajo nuevo, **IM, Bu, CR, AH, FP**; el trabajo recientemente hecho se debe proteger con lona **Bu.**

### Heladas.

**55. Congelación.** No se debe hacer concreto ó mortero cuando la temperatura es menor de 2° C, en la sombra; el trabajo de concreto se debe suspender desde el 20 de noviembre hasta el 1.° de abril; durante la temperatura de congelación, no se debe mezclar ó depositar ningún concreto sin permiso del ingeniero, **IM, Bu**; el hielo y la escarcha deben quitarse, el agua y la arena se deben calentar, el granzón se pondrá al vapor, el trabajo debe cubrirse conservándolo caliente por tubos de vapor, **Lv**; el concreto no se debe colocar cuando está helado; si está armado, se debe conservar á más de 0° C, durante $<$ 48 horas después de colocado, el uso de arena y agregado helados está prohibido, **Ch.** No se permite la colocación cuando la temperatura es $>$ 0° C, **Un, AH, BR,** $<$ 0° C, **OD**; $<$ — 1° C, **CR,** $<$ — 2° C, **TR, FP**; cuando haya probabilidad de que hiele antes de la fragua, **Wv**; antes de la fragua final, **OD**; antes de que fragüe lo suficiente para impedir que se dañe, **BR, CR.** El concreto que se hiele después de colocado debe quitarse, **Un.** No se debe colocar el concreto cuando la temperatura sea menor de — 7° C; el agua se debe calentar cuando la temperatura sea menor de — 2° C, **MC.** El empleo de materiales helados está prohibido; la colocación del concreto debe protegerse de la congelación, **Ph.**

**56. El concreto de cemento natural** no debe nunca estar expuesto á la helada hasta después de estar completamente endurecido y seco, **T y T.**

**57.** « Ningún concreto, excepto el que se coloca en grandes masas, ó muros fuertes cuya sup no importe que luzca bien, debe exponerse á la helada hasta que no esté seco y duro. Los materiales que se emplean en la masa de concreto en tiempo de congelación no deben contener escarcha. Las superficies deben protegerse de la escarcha. Las partes de superficie de concreto que se hayan helado, se deberán quitar antes de colocar concreto nuevo. » **T y T.**

**58. Las armaduras** bajo el concreto que se hayan colocado en tiempo de congelación, « deben **permanecer** hasta que todas las trazas de la helada hayan desaparecido del concreto, y que el endurecimiento natural del concreto haya llegado al punto de seguridad », **CH, Ph.**

### Humedecimiento.

**59. Humedecimiento.** El concreto nuevamente colocado debe protegerse del sol (con tablas ó tela alquitranada, **FP, Hb, IM**); conservándole húmedo; **Mc, IM**; $<$ dos semanas ó hasta que se cubra de tierra, **F**; $<$ 10 días, **SE, AH**; 6 días, **CR**; 3 días, **EW**; 48 horas, **BR**; hasta que fragüe, **Wv**; hasta que fragüe fuertemente, **Hb**; las superficies no deben alisarse hasta que se continúe el trabajo, **CR**; con tela alquitranada húmeda $<$ 3 días. Al completarse una sección del muro cúbrase la parte superior con una capa gruesa de arena húmeda, regando con agua la masa del muro hasta que el concreto haya fraguado completamente, **IM**; el concreto debe empaparse dos veces por día, incluyendo los domingos, durante una semana después de la colocación, en época de calor, **Ch, Ph.**

**60.** Humedézcase regando con una regadera fina á cortos intervalos ó cubriéndolo con tela húmeda, etc., **G.**

### Quitada de las armaduras.

**61.** Las armaduras deben dejarse en su lugar $<$ 4 días, **IM**; $<$ 7 días; más tiempo si lo requiere el ingeniero, **Lv**; 72 horas, **OD**; 48 horas, **AH, BR**; hasta que el concreto haya estado en ellas por lo menos 36 horas, **WH**; hasta que el ingeniero autorice la quitada, ó hasta que el concreto se haya endurecido, **Ci, b**; hasta que el concreto pueda soportar su carga con seguridad, **Ms**; las armaduras se quitarán después de 48 horas, **SE.**

**62.** Los puntales debajo de los pisos y techos deben permanecer en su lugar $<$ 2 semanas. Las armaduras de columnas, $<$ 4 días; para planchas, vigas y tra-

viesas, < 1 semana y por lo menos hasta que el piso pueda soportar su propio peso. « Ninguna carga ó peso se colocará en parte alguna de la construcción en que dichos apoyos ó cimbras se hayan quitado. » **Ch, Ph.**

**63.** El tiempo para la quitada de las armaduras y apoyo es de 24 horas á 60 días, dependiendo de la temperatura y otras condiciones atmosféricas y del inspector de edificios, **Un.**

**64.** Hasta que el concreto no esté duro.

| | Tiempo mínimo, días: abril 1.° á dic. 1.°; | dic. 1.° á abril 1.° |
|---|---|---|
| Planchas y dinteles, columnas y paredes monolíticas | 10 | 15 |
| Postes y apoyos inferiores para maderas y vigas | 14 | 21 **L.** |

**65.** Las armaduras bajo concreto colocadas **en tiempo de congelación** « deben permanecer hasta que todas las señales de escarcha desaparezcan del concreto y el endurecimiento natural de éste haya llegado al punto de seguridad », **Ch, Ph.**

## Acabado de las superficies, construcciones á prueba de agua, etc.

**66.** El acabado se conserva terso por manipulación durante la colocación, etc. El concreto, libre de agregado grueso, debe colocarse pegado á las armaduras, despegándolo de ellas con una pala chata, que se introduce entre el concreto y la armadura (la armadura se humedece con agua, **BR**), el concreto se apisona con un pisón de hierro, con faz inferior de 5×15 cm, **AH, BR**; el acabado se hace retirando el granzón hacia atrás por medio de tenedores, **HB**; ó **palas, FP**; las faces se alisan por frotamiento, **TR, Hb**; con un pedazo de madera, ó piedra blanda, **TR**; los vacíos se rellenan con mezcla, **Hb, TR, CR**; el enlucido se permite solamente en una cavidad ocasional y accidental en que el enlucido no esté expuesto al efecto de la escarcha, **CR**. Véase § 79. El mortero de cemento Portland de 1:3, se coloca simultáneamente con el grueso del muro, **CR**. Para muros, el mortero de cemento Portland, muy seco, de 3.5 cm de espesor, **TR**.

**67.** En las caras descubiertas, se deben quitar las armaduras antes que el concreto se endurezca; la superficie (1) se frota con mortero de 1 volumen de cemento Portland, 2 volúmenes de arena, aplicado con un tapón de coleta, y alisado con una brocha de encalador, ó (2) frotado con una brocha de alambre duro, y una mano delgada de pasta fina de cemento Portland, alisada con una brocha de encalador, **NO, Co**; el acabado pulido de los lados se produce apisonándolos muy bien contra las superficies de las armaduras, **SE.**

**68.** Las superficies que no queden contra las armaduras, se cepillarán y alisarán con cuchara, **NO.**

**69.** Los vacíos ú otras imperfecciones que aparezcan al quitar las armaduras, se corregirán á expensas del contratista, que debe quitar y reemplazar el trabajo que no sea satisfactorio, si fuese preciso, **F.**

**70. Para pisos y techos del estanque de mezclar.** Mortero duro, de 1 volumen de Portland, 1 volumen de cernidura finas de piedra que pasan por un anillo de 10 mm, libre de polvo, marga, etc., de 2.5 cm de espesor, colocado antes de la fragua inicial del concreto. Se raspa y se alisa la superficie con cuchara. Se cubre y riega durante 3 días, **CO.**

**71. Los andenes y partes superiores de los parapetos** se alisan con una capa de mortero > 6 mm de espesor, consolidada con el concreto « sobreponiéndole planchas fuertes de 10 cm de espesor y apisonándolas con pisones de hierro fundido de 18 kg, hasta que sus extremos estuvieron en contacto con los extremos de los armaduras », **SE.**

**72. Para los muelles, pedestales y estribos.** En las superficies expuestas al aire ó al agua, mortero de cemento Portland de 4 cm de espesor, 1 de cemento 2 de arena, subido simultáneamente con el concreto en zonas de 25 á 28 cm de ancho por medio de armaduras de láminas de acero de 6 mm, 30 cm de ancho, 1.20 á 1.50 m de largo, colocadas rodeando la obra, á 4 cm de las armaduras, y separadas á cada 30 cm por bloques de madera, cubriéndose los extremos de las planchas, ligeramente, unos sobre otros, **WH.**

**Para lista** de especificaciones para concreto, véanse págs. 1401-02.

**73. Secciones de cloacas**, 1 de cemento, 2 de arena, no más de 13 mm de espesor, colocada al mismo tiempo que el concreto, **Lv**.

**74. En las molduras, cornisas, etc.** Mortero plástico colocado contra las armaduras de construcción fina, á medida que se coloca el concreto; no se permite enlucido exterior, **SE, T y T**; no se hará enlucido á menos que sea especialmente permitido.

**75. Acabado de la parte superior.** El concreto se llevó hasta 9 cm menos de la elevación requerida, y mientras éste estaba todavía sin fraguar y blando, se añadieron 7.5 cm de concreto más fino, que se apisonó y se amasó para formar un monolito con el concreto de abajo; luego se añadió 12 mm de 1 : 3 (1 : 2, **AH**) y se rebajó á la altura requerida con una vara larga de madera, de filo recto, **AH, BR**.

**76. Coronamiento final.** Mientras que la base de concreto está aún blanda, sin fraguar y pegajosa, se extiende mortero (que deberá tener 2.5 cm de espesor al alisarlo), se nivela, y se golpea con madera; se rebaja, y se alisa con una regla y se pule con una cuchara fina de enlucir; se cubre con tablas ó tela alquitranada hasta fraguar firmemente, luego se cubre con arena, se debe conservar húmeda por varios días, **FP**; el mortero de $<$ 2.5 cm de espesor, de 170 kg de cemento Portland para 300 lit de arena, se aprieta encima del concreto apisonado antes que éste empiece á fraguar, se rebaja con un filo derecho, se cepilla y se alisa con cuchara de encalador, **CR**; mortero de cemento Portland de 1 : 2, de 2.5 cm de espesor, **TR**; la superficie se forma empujando las piedras de la superficie hacia atrás, **Hb**.

**77. Acabado de superficies imitando granito**, para la parte superior de las pilas, pedestales y estribos; 1 parte de Portland, 2 partes de arena de granito gruesa limpia ó cerniduras finas de granito, 3 partes de astillas de granito, que pasen por un anillo de 12 mm. Se alisa con una regla de enlucido, **WH**.

**78. Para hacerlo impermeable.** Una mano fuerte de mortero semilíquido de 1 parte de cemento, 1/2 parte de cal apagada, 3 partes de arena. Esta mano se debe dar como un enlucido fino. Cuando haya fraguado, añádase una mano gruesa de pasta líquida de cemento puro, **CS**.

**79. Enlucido con cemento.** No se permite en las caras descubiertas, **AH, CS**. Las caras interiores de las enjutas rellenas, bien humedecidas y enlucidas con mortero de 1 de cemento : 2, 5 arena, **CS**. Véase § 66.

## Piedra artificial.

**80. (a) Para las molduras finas, etc.** Los moldes se enlucen con mortero semilíquido 1 de cemento, 2 de arena fina aguda, respaldada con concreto semihúmedo de 1 : 2 : 4, ó 1 de cemento para 6 de granzón que pase por el anillo de 10 mm. El respaldo de concreto apisonado por capas delgadas. **(b) Para las superficies planas sencillas.** El concreto se apisona en los moldes. Se quitan los moldes. Las superficies descubiertas se aplanan con mortero hasta un acabado liso como en (a). No se debe dejar ningún mortero sobre la cara. Usese solamente lo suficiente para llenar los poros y darle un acabado terso, **CS**.

## Resistencia, etc., que se requieren.

(Las resistencias, etc., en kg/cm cuad, á menos que se especifique de otro modo.)

**81. Compresión máxima** después de endurecerse durante 28 días, $<$ 140, **Un, Mh**.

**82. Esfuerzo cortante máximo** correspondiente á la compresión de 140, **14, Un**.

## Cargas máximas permitidas.

**83. Para las cargas estáticas** sobre un concreto de cemento Portland de 1 : 6.

| | Carga máxima permitida kg cm cuad ** |
|---|---|
| Compresión, superficie de concreto > el área cargada | .325.s* = 45.7 |
| — en columnas, largo > 12 diámetro | .225.s = 31.6 |
| — — armadas sólo longitudinalmente | .225.s = 31.6 |
| — — con sunchos | .270.s = 38.0 |
| — — con sunchos, con barras longitudinales de 1 á 4% | .325.s = 45.7 |
| — — con unidades de columnas de acero que cubren enteramente el corazón de concreto | .325.s = 45.7 |
| Módulo de ruptura (módulo de elasticidad, E, constante) | .325.s = 45.7 |
| — — adyacente á los soportes (E constante) | .375.s = 52.7 |
| Esfuerzo cortante (ninguna compresión normal á la superficie del esfuerzo cortante, recibiendo la armadura la tensión normal) | .060.s = 8.4 |
| — — combinado con compresión igual | .162.s = 22.8 |
| Adhesión, barras lisas | .040.s = 5.6 |
| — alambre desplegado | .020.s = 2.8 |

**JC.**

**84. Compresión.** Véase también § 146.
A, excluyendo los esfuerzos de la temperatura,
B, incluyendo los esfuerzos debidos á los cambios de temperatura de 22° C.

Una vuelta en 5 á 7 veces el tamaño nominal, **F.**
Torcidas uniformemente con maquina, variando el área de sección transversal mínima en no más de 2.5%, **NO, Co.**

**99. Barras redondas, corrugadas, etc.**, que tengan la misma área total de sección neta que las barras cuadradas ó torcidas, **NO.**

**Requisitos.**

**100. El hierro y acero** « deben satisfacer las Especificaciones Modelo de los Manufactureros, revisadas feb. 3, '03 », **Ph.** Véase pág. 946 y 947.

**101. Acero, manufactura y dureza.** Mediano, Martín Siemens, **NO, Bu, Co, Ci**; suave, **Lv**; blando ó mediano, **CS.**

**102. Resistencia á la tensión máxima**, en miles de kg/cm cuad: 3.64 á 4.32, **F**; 3.8 á 4.48, **Un, Mh**; mediano, 3.50 á 4.55, **Ci, a**; mediano, 4.20 á 4.76, **CS**; blando, 3.78 á 4.34, **CS**; 3.85 á 4.55, **Lv, T y T**; < 3.85, **NO**; 3.99 á 4.55, **Co, a**; 4.20 á 4.90 antes de torcer, **Co, b**; 4.20 á 4.90, **Bu.**

**103. Compresión máxima.**

| Mezcla. | 1:1:2 | 1:1.5:3 | 1:2:4 | 1:2.5:5 | 1:3:6 |
|---|---|---|---|---|---|
| kg/cm cuad = | 203 | 168 | 140 | 122 | 105 |
| $n = E_s/E_c =$ | 10 | 12 | 15 | 18 | 20 |

**Ch.**

**104. Fractura**, sedosa, uniforme en color y contextura, **Co.**

**105. Límite de elasticidad** < que la mitad de la resistencia máx de tensión, **G.**

**106. Coef de elasticidad**, 2,100,000 kg/cm cuad, **CS.**

**107. Cociente, n, de los coef de elasticidad.**

$$n = \frac{E_s}{E_c} = \frac{\text{coef de elasticidad del acero}}{\text{coef de elasticidad del concreto}}.$$

$n=12$, **Mh.** « Si no se encuentra por pruebas directas », en las vigas y planchas $n=15$; en las columnas, $n=10$, **MS**; con la resistencia de compresión máxima = 140 kg/cm cuad, $n=18$, **Un.**

Concreto de granzón ó piedra, $n=12$; escoria, $n=15$, **Ph**; ceniza, $n=30$, **Ph, Ch.**

**108. Estiramiento**, % mínimo, en 20 cm, 25, **F, Lv, NO, Co, a**; 22, **Co, b, Ci, a**; 20, **Un, Mh**; blando, 25; mediano, 22, **CS** $\frac{98{,}000}{\text{resistencia á la tensión}}$, **T y T.**

**109. Prueba de flexión.** Frío, **F, Lv, Bu, CS**; caliente, frío, ó apagado, **NO, Co, a**; 180° alrededor de un diámetro = al espesor de la barra, **F, NO, Bu, Co, CS**; (antes de deformarlos, **F**); como un diámetro = al doble del grueso de la barra, **Lv**; (después de deformarla, **F**); acero blando, chato, **CS**; frío, 90° sobre un diámetro = dos veces el espesor de la barra en acero > 19 mm de diámetro; más de un diámetro = 3 × el espesor de la barra en acero > 19 mm de diámetro, **Ch.**

**Presiones máximas permitidas en el acero.**

Las presiones en kg/cm cuad á menos que se indique de otra manera.

**110. Tensión**, 1,120, **Mh, Ph, JC**; (hierro 840, **Ph**); un tercio del límite de elasticidad, pero no más de 1,260, **Ch**; blando, 840; mediano, 1,050; muy rico en carbón, 1,260, **L.**

**111. Esfuerzo cortante**, 700, **Mh**; 840, **Ch.**

**112. Compresión** = compresión en el concreto × $\frac{\text{coef de elasticidad del acero}}{\text{coef de elasticid del concreto}}$, **Ch.**

« En los arcos, los anillos de acero que están bajo una presión que no exceda de 1,260 kg/cm cuad, deben estar en capacidad de soportar todo el momento de flexión del arco sin la ayuda del concreto, y tener un área de rebordes ó proyecciones de < la 150.ª parte del área total del arco en la clave. La presión real cuando están incrustadas y obran en combinación con el concreto no debe exceder de 20 veces la presión permitida sobre el concreto. »

« En las planchas, vigas, vigas armadas, pisos y muros, sometidos á esfuerzos transversales, supondremos que el acero soporta toda la presión sin ayuda del concreto, y que tendrá un área suficiente que iguale á la resistencia de compresión del concreto de 6 meses compuesto de 1 parte de cemento Portland, 3 partes de arena y 6 partes de piedra quebrada. »

« En los muros ó postes sometidos á compresión solamente, no se hará concesión en la resistencia del acero incrustado que se usará solamente como una precaución contra las cuarteaduras debidas á la contracción ó cambios de temperatura.

**Para lista** de especificaciones para concreto, véanse págs. 1401-02.

« En los estanques, el acero incrustado bajo una presión que no exceda de 1,050 kg/cm cuad deberá estar en capacidad de soportar toda la presión del agua sin ayuda del concreto », **CS.**

El estiramiento en el servicio de no más de .2%. **Ch.**

**113. Adhesión entre el acero y el concreto.** Se supone $>$ que el esfuerzo cortante permitido en el concreto, **Mh, Ms**; $<$ que el esfuerzo cortante en el concreto, **Un**; en el concreto de granzón ó piedra, 3.5 kg/cm cuad; en el de escoria, 2.8; en el de ceniza, 1.05, **Ph.**

**114.** En el concreto de 1 : 2 : 4, máxima, kg/cm cuad :

| | |
|---|---|
| en las barras cuadradas ó redondas, lisas, acero de construcción. | 4.9 |
| acero muy rico en carbón..... | 3.5 |
| en barras chatas, lisas, razón de los lados $>$ 2 : 1..... | 3.5 |
| en barras torcidas, $<$ 1 torcida en 8 diámetros..... | 5.6 |

en barras de forma especial,

.25 × la adhesión máxima determinada por la prueba; máxima.... = 7 **Ch.**

**115.** « **Cuando se excede la presión permitida,** debe hacerse una concesión para transferir la resistencia del acero al concreto », **Un, Mh, Ph.**

**116. Largo y recubrimiento.**

Las barras longitudinales **de no menos de 9 m**, si es posible, **Lv.**

En las vigas, barras de **largo sencillo**, si es posible, **MO, Co, Ci.**

**Si están recubiertas :**

| | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| Lado de la barra en mm. | 6 | 10 | 12.5 | 15 | 19 | 22 | 25 | 28 | 32 | |
| **Recubrimiento** en cm. | 15 | 25 | 33 | 45 | 50 | 55 | 65 | 75 | 80 | **NO.** |
| | 15 | 23 | 30 | 37. | 45 | 50 | 55 | 60 | 67 | **Co.** |

Recubrimiento = $<$ 20 × diámetros de la barra $<$ 30 cm, **Ci.**

**Extremos**, no menos de 5 cm fuera de cualquier superficie, **Lv.**

Las barras se llevan hasta las orillas extremas de las superficies no acabadas.

Las barras se prolongan hasta 2.5 cm de las superficies acabadas, **Co.**

Las barras del piso se prolongan 10 cm más allá de la cara de la pared que soporta el piso.

Las barras de las vigas $<$ 20 cm más allá de la cara de la pared que soporta el piso, **NO, Ci.** Véase Espacio libre más abajo.

**117. Protección.** Si se interrumpe el trabajo, las barras, ya colocadas, deben protegerse con coleta ó papel alquitranado. Los extremos que vayan á estar descubiertos largo tiempo, deberán cubrirse con una mano gruesa de mezcla líquida de cemento puro, **F, Lv.**

## Permisos.

**118.** Planos y especificaciones, completamente detallados, de la composición de concreto, se deben presentar al inspector de edificios, **Ch, Un, Mh, Ph.**

La concesión del permiso no implica la aceptación de la construcción, **Ch.** Para las pruebas que se requieren, véanse págs. 1413-14.

**Espacio libre.** Véanse también §§ 116, 134, 144, 149.

**Distancia, t, entre el acero y la superficie del concreto.**

**119. En las columnas y vigas,** $t$ $<$ 4 cm, **Ch, Ms**; en las planchas $t$ $<$ 12 mm $<$ el diámetro de la barra, **Ch**; $t$ $<$ 2 cm, **Ms**; $t$ $<$ 1.5 × el diámetro de la barra, **JC.**

**Ejes de las barras** separados del exterior del concreto $<$ diámetro de barra, **CS.**

Edificios á prueba de fuego, véanse §§ 120-128.

**Distancia libre entre las barras** $<$ 1.5 × la dimensión máxima de sección de la barra, **Ch, JC. Distancia libre entre dos capas de barras,** $<$ 12 mm, **JC.**

**120. En los edificios á prueba de fuego** (§§ 120-128), la construcion de concreto armado no se debe aprobar « á menos que se hayan hecho pruebas satisfactorias con fuego y agua bajo la inspección de esta Oficina », **Mh.**

Puede aceptarse si se proyecta como lo prescribe el Código, con tal que :

(1) El agregado sea de « ladrillos quebrados muy bien cocidos, ó terracotta, escoria de hornos limpia libre de materia combustible, piedra limpia, quebrada ó escoria de hornos, ó granzón limpio, junto con arena silícica, limpia, si se requiere la arena para producir una mezcla densa y compacta »; **Un.** (Los otros Códigos que se citan especifican menos variedades permitidas de agregados.) El agregado que pase por mallas de 10 mm **Ch**; por anillo de 25 mm, y 25% de agregado $>$ la mitad del tamaño máximo, **Ph.**

(2) El espesor mínimo, $t$, del concreto que rodea las piezas de la armazón, será como sigue, en que $d$=el diámetro paralelo á $t$ :

**121.** Cuando $d > 6$ mm, $t=25$ mm; cuando $d > 6$ mm, $t=4\ d$. En todo caso $t > 10$ cm, $t <$ el espesor requerido para las construcciones más $a=25$ mm en las columnas y vigas laminadas, $a=20$ mm en las planchas ó baldosas para piso; « pero por esto no se entenderá que se aumenta el espesor total del concreto protector como se indica en la presente », **Un.**

**122. En las vigas laminadas y columnas,** $t=5$ cm; en las vigas, $t=4$ cm; en las planchas ó baldosas para pisos, $t=2.5$ cm, **JC.**

**123.** En las columnas monolíticas, los 4 cm exteriores se considerarán como cubierta protectora, y no se incluirá en la sección efectiva, **JC.**

**124. En las vigas armadas y laminadas,** en la parte inferior, $t=5$ cm; en los lados, $t=4$ cm. Barras de baldosas inferiores, $t=2.5$ cm. En las columnas, $=5$ cm, **Ch, Ph.**

**125.** « Si se coloca una estructura de metal suplementaria en el concreto que rodea la armazón, simplemente para sujetar el concreto, el espesor del concreto que está debajo de la armazón podrá reducirse en 12 mm, y no se considerará la estructura como metal de la armazón », **Ch.**

**126.** En las vigas de piso y de techo, $t=2.5$ cm; en las vigas laminadas de piso y de techo, y en las vigas que soportan mampostería, $t=2.5$ cm; en cualquiera otra parte, 5 cm; en las columnas que solamente soportan pisos, $t=7.5$ cm; en las columnas construídas dentro de los muros ó que los soporten, 10 cm, **Ms.**

**127. Concreto de ceniza,** para construcción á prueba de fuego, $t$ lo mismo que para el concreto de piedra; para la construcción de grandes talleres ó de edificios que han de arder con lentitud, en las columnas, $t=5$ cm; « en las vigas armadas, laminadas y otras piezas de construcción de acero ó de hierro », $t=4$ cm. La cubierta debe tener « ligazones de metal ó tela de alambre incrustada en y alrededor » de aquellas piezas; las ligazones, si son de alambre, no deben ser menores que el n.º 8, y á no menos de 40 cm de separación, **Ch.**

**128.** Los ángulos de las columnas, vigas armadas, vigas laminadas, deben biselarse ó redondearse, **JC.**

## Columnas.

**129.** A las columnas se les debe dar $<$ de 2 horas para asentarse y contraerse antes de colocar las vigas laminadas sobre ellas, **JC.**

**130.** « Las **reglas** para calcular las columnas de concreto armado pueden **formularse de vez en cuando** por el inspector de edificios con la aprobación de la Junta de apelación », **Ms.**

**131. Se supone que el concreto y el acero se contraen** « en la misma proporción », **Ms.**

**132. El concreto y el acero se comprimieron** en la relación, $n$, de sus coef de elasticidad, **JC.**

**133.** Las barras se sujetan á intervalos suficientemente cortos para impedir que se doblen, **Ms.** Véase § 136.

**134.** Los 4 cm exteriores deben considerarse como cubierta protectora y no incluirse en la sección efectiva, **JC.**

### Columnas armadas.

L=largo; $d$=diámetro ó lado menor.

**135.** El concreto armado puede usarse en las columnas cuando L $>$ 12 $d$, **Ch, Un, Mh**; $>$ 15 $d$, **JC**; y cuando el área de la sección transversal $<$ 413 cm cuad, **Ch.** Si L $>$ 15 $d$, se deberá disminuir en proporción la presión permitida **Ph.**

**136. Requisitos. Las barras deben ligarse á intervalos** no más grandes que $d$, **Un, Mh, Ph**; no más grandes que 12 $d$, no más de 45 cm, **Ch.** Véase § 133.

**Para lista** de especificaciones para concreto, véanse págs. 1401-02.

**137.** Las barras longitudinales no se deben considerar como recibiendo **compresión directa, Ph.**

**138. El área de la sección transversal** combinada de las barras de compresión $>$ 3% del área de la sección transversal de la columna, **Ch.**

**139.** Cuando no se requieren barras de compresión, el área de la sección transvesal de las barras deberá ser $<$ .5% del área de sección transversal de la columna; no menos de 6 cm cuad, **Ch.**

**140.** La dimensión mínima de la barra menor no debe ser menos de 12 mm, **Ch.**

**141.** Las barras deben prolongarse en la columna por arriba ó por abajo, recubriendo las barras ahí situadas lo suficiente para desarrollar la resistencia en la barra por la unidad de adhesión permitida, **Ch.**

**142. Carga excéntrica ó transversal.** Esfuerzo máximo de las fibras, incluyendo (1) la compresión directa, (2) la flexión debida á la compresión directa, (3) la excentricidad, y (4) la carga transversal que no sea mayor que la resistencia permitida á la compresión. La carga excéntrica se « considerará como afectando excéntricamente tan sólo el largo de la columna que se prolonga hasta el punto inmediato inferior en el cual la columna esté fuertemente sujeta en la dirección de la excentricidad », **Ms.**

**143. Una columna** monolítica con una viga armada ó laminada **rígidamente unida á ella**, debe resistir, además de las cargas directas, un momento=al momento no equilibrado en la viga sobre la columna, **Ch.**

**144. Columnas con sunchos.** El concreto puede someterse á esfuerzos hasta el 25% de la resistencia máxima con tal que :

(1) El área de sección transversal de la armazón vertical $<$ el área de la armazón espiral $>$ 5% del área entre los sunchos;
(2) Percentaje de los sunchos en espiral $<$ .5, $>$ 1.5;
(3) Separación de los sunchos en espiral uniforme y $>$ .1 × diámetro de la columna, $>$ 7.5 cm;
(4) Los espirales sujetos de tal manera á las verticales, en cada intersección, que conserven sus formas y posición;
(5) La distancia entre las verticales $>$ 22 cm, $>$ $\frac{1}{8}$ de la circunferencia de la columna entre los aros.

Se puede « suponer que los sunchos aumentan la resistencia del concreto en un equivalente de 2.5 × la cantidad de sunchos espirales que se consideren como refuerzo vertical ». El concreto, fuera de los sunchos, no se considera como parte de la sección efectiva de la columna, **Ch.**

**145.** « Los esfuerzos que obran serán asunto de consideración especial para el comisionado ó inspector de edificios », **Un.**

**146. Unidad de compresión** permitida=70 kg /cm cuad del área entre los aros, **Ph.**

**147.** El percentaje de barras longitudinales y la distancia entre los aros deben ser tales que el concreto pueda desarrollar este esfuerzo con un factor de seguridad de 4, **Ph.**

**148.** « No debe considerarse que los sunchos ó bandas aumenten directamente la resistencia de la columna », **JC.**

**149.** Espacio libre entre las bandas y aros $>$ .25 × diámetro de la columna incluída, **JC.**

**150. Columnas armadas con acero de construcción.** El concreto puede someterse á $\frac{1}{4}$ de la resistencia máxima, con tal que: (1) el área de sección transversal del acero no sea menos de 6 cm cuad; (2) los espacios del enrejado ó listones no deben ser mayores que el ancho mínimo de la columna, **Ch.**

## Vigas y pisos.

**151.** La teoría común de las vigas es aplicable, **Un, Ch, Mh, Ph.**

**152.** Se supone que el acero soporta todas las tensiones directas, **L, Un, Ch, Ms, Mh, Ph.** Las tensiones en el concreto deben tomarse en cuenta al calcular las deflexiones, **JC.**

**153. La curva del esfuerzo de estiramiento** del concreto en compresión se supone que sea una línea recta, **Ch, Ph,** $n = E_s/E_c = 15$; para las deflexiones, $n = 8$ á 12, **JC.**

**154.** Con 140 kg/cm cuad de esfuerzo máximo en fibras, esta curva puede tomarse como: (*a*) una línea recta; (*b*) una parábola, con eje vertical y el vértice en el eje neutro de la viga; ó bien (*c*) una curva empírica, que incluye un área ¼ mayor que si fuera una línea recta, y con el centro de gravedad á la misma altura que el área en (*b*), **Un.**

**155. Esfuerzos.** Una carga=4×la carga total de trabajo, comprime el acero hasta su límite elástico, y el concreto á 140 kg/cm cuad, **Un.** Proyecto « fundado en la suposición de una carga cuádruple que la carga total », **Ph.** (La carga total= carga muerta ordinaria más la carga viva ordinaria, **Un, Ph.**)

**156. La adhesión**, entre el concreto y el acero, se supone que es suficiente para hacerlos obrar conjuntamente, **Un, Ch, Mh, Ph.**

**157. El metal descubierto** no se considera al calcular la resistencia, **Un, Ch, Ph.**

**158. La luz**=distancia de centro á centro de las planchas de cimiento ú otros soportes, **Ms, JC.** Si la viga está sujeta al lado de una columna, se mide la luz hasta el centro de la columna, **Ms.** La luz > (la luz neta+la altura de la viga ó plancha), **JC.**

**159. Los esfuerzos térmicos y la contracción** se deben prever con la introducción del acero, **Ch, Ph.** « Los esfuerzos iniciales en la armazón, debidos á la contracción ó expansión del concreto, pueden despreciarse », **JC.**

**160.** Cuando el **esfuerzo cortante** que se desarrolle exceda el límite concedido al concreto, se debe introducir el acero para que reciba el exceso, **Un, Mh, Ph, JC.**

**161.** Valores permitidos para las resistencias al esfuerzo cortante: kg/cm cuad.

| | |
|---|---|
| (*a*) Con barras horizontales solamente | 2.8 |
| (*b*) Con parte de la armazón horizontal en forma de barras encorvadas, « dispuestas debidamente con respecto á las resistencias al esfuerzo cortante » | > 4.20 |
| (*c*) Con armazón completa para el esfuerzo cortante | > 8.40 |

**JC.**

En (*c*) se puede suponer que el concreto recibe ⅓ del esfuerzo cortante, los ⅔ restantes los recibirán las barras encorvadas ó los estribos (con preferencia ambos) que soportan su parte en una distancia horizontal=el espesor de la viga, **JC.**

**162.** Los intervalos longitudinales de los estribos ó barras encorvadas > .75×el espesor de la viga, **JC.**

**163. La pega del acabado de cemento,** añadida en la parte superior de las planchas, vigas armadas y laminadas, **no se debe incluir** al calcular la resistencia « á menos que se coloque íntegramente con la masa del concreto », y sin calcularle mayor unidad de resistencia que la del concreto, **Ch.**

**164. Armazón de tejido.** « Cuando el esfuerzo cortante vertical, medido en la sección de una viga sencilla ó laminada, entre los centros de acción de los esfuerzos horizontales, es > .02×la presión máxima directa por cm cuad, se empleará la armazón suficiente de tejido para que reciba el exceso. La armazón de tejido deberá extenderse desde la parte superior hasta la parte inferior de la viga y arrollarse ó unirse á la armazón horizontal. La armazón horizontal, que recibe las presiones directas, no se considerará como armazón de tejido », **Ch.**

**165. El acero en los lados de compresión de las vigas sencillas y laminadas.** « Cuando se use el acero en el lado de compresión de las vigas sencillas y laminadas, se deberán ligar las barras de acuerdo con los requisitos de las columnas verticales armadas, con estribos que las liguen á las barras de tensión de las vigas », **Ch.**

**166.** Cuando el acero, ó el hierro, están del lado de la compresión de la viga, la porporción del esfuerzo recibida por el acero, ó el hierro estará en la relación que existe entre el módulo ó coef de elasticidad del acero, ó del hierro, y el módulo de elasticidad del concreto, con tal que las barras estén bien ligadas á los estribos que las conectan con las barras inferiores de las vigas », **Ph.**

**167.** Cuando se empleen planchas con vigas sencillas y laminadas, se tratarán éstas como si fuesen vigas en T, obrando entonces una parte de la plancha como un reborde, **G.**

**Para lista** de especificaciones para concreto, véanse págs. 1401-02.

**168. Parte, F, del ancho de la plancha ó losa, que obra como reborde,**

$t$=espesor de la losa; L=luz de la viga, armada ó laminada;
$b$=ancho de la viga; S=distancia de centro á centro entre las vigas.

F se « determinará suponiendo que en cualquier sección plana horizontal del reborde, los esfuerzos están distribuídos como las ordenadas de una parábola, con el vértice en la curva del esfuerzo de alargamiento y su eje en un plano vertical longitudinal por el centro de la parte vertical de la T ». Dicha parte debe reforzarse con barras cerca de la parte superior, en ángulo recto con la viga. **Un.**

**169.** F depende de la resistencia al esfuerzo cortante, $F > 20\,t$, **Ph**; $F > 10\,b$, **Mh.**

**170.** F regida por la resistencia al esfuerzo cortante entre la plancha y la parte vertical; $F > S\left(1-\frac{S^2}{L^2}\right) > L/3$, $> \frac{3}{4}$ S. Para suponer que obra de aquella manera, la plancha debe vaciarse al mismo tiempo que la parte vertical, **Ch.**

$$F > L/3, > S, \textbf{Ms}; > L/4 > 8\,t + b, \textbf{JC}.$$

**171.** Las vigas en T deben armarse contra el esfuerzo cortante á lo largo del plano de unión entre la parte vertical y el reborde, **Un, Ph**; usando estribos en todo el largo de la viga, **Ph.**

**172.** Las partes verticales de las vigas deben ser *monolíticas* con las losas del piso, **Un, Ph.**

**173.** « Cuando las vigas laminadas de concreto armado soportan vigas sólidas de cóncreto armado, la parte superior de las losas, ó planchas, del piso, que obran como reborde de la viga, debe ir reforzadas con barras, cerca de su superficie superior, colocadas en ángulo recto á la viga, para que aquella parte de la plancha pueda transmitir las cargas locales directamente á la viga laminada y no á las vigas sostenidas por éstas, para impedir que se sumen los esfuerzos de compresión producidos por la acción simultánea de la plancha del piso y del reborde propio de la viga. » **Un, Ph.**

**Momento, M.** Véase también §§ 178, 179.

**174.** W=carga por m cuadrado; L=luz, en m. En las planchas soportadas libremente, L=abertura libre+espesor; en las planchas continuas, L=distancia entre los centros de los soportes.

**175.** Con cargas concentradas, ó especiales, calcúlese y provéase para los momentos y esfuerzos cortantes en la posición peligrosa de la carga, **Ch.**

Para la carga muerta; M obtenida de la carga muerta efectiva.....
Para la carga viva, sobre los soportes; M obtenida de la viva efectiva..... } cubriendo todas las luces al mismo tiempo.

Para la carga viva, entre los soportes, M = máx obtenido de la carga viva cubriendo 2 luces consecutivas ó 2 alternadas al mismo tiempo.

Cuando todas las luces son iguales, sea $M_1$=mínimo del momento de la carga viva en el centro de la luz. Entonces,

para las luces intermedias, $M_1 = \frac{WL^2}{12}$

para las luces extremas, $M_1 = \frac{WL^2}{10}$

La suma de los momentos de carga viva en un soporte en el centro de la luz, $< \frac{WL^2}{6}$, **Ch.**

**Continuidad.** Véase también § 175.

**176. Las vigas sencillas y laminadas,** se supone simplemente apoyadas en los extremos; no se hace concesión por la continuidad, **Un, Mh.**

**177.** Las vigas, etc., se calculan como si estuviesen soportadas simplemente, ó como continuas, según los casos, **Ch, Ms.**

**178. Las planchas de piso continuas,** armadas en la parte superior sobre los apoyos, pueden considerarse como vigas continuas. Con cargas uniformemente distribuídas, el momento, M, se calculará en no menos de .1 WL; .05 WL para las planchas cuadradas de piso armadas en ambas direcciones y apoyadas en todos sus lados, **Un, Mh, Ph.**

**179. En las losas ó planchas del piso adyacente á los muros**; si la losa está armada en una dirección, $M=\frac{WL}{8}$; si es cuadrada y está armada en ambas direcciones, $M=\frac{WL}{16}$; **Ph.**

**180. Las losas** para pisos calculadas y armadas como continuas sobre los soportes. Si el largo de la losa, $>$ 1.5 × su ancho, la armazón transversal soportará la carga entera. « Las losas ó planchas cuadradas pueden muy bien armarse en ambas direcciones », **J. C.**

**181.** En las vigas y planchas continuas $>$ 2 luces, los momentos de flexión en el centro y en los apoyos, para ambas cargas, viva y muerta, son como sigue :

En las losas á planchas para piso y las luces interiores de vigas continuas..... $M=wL^2/12$
En las luces extremas de las vigas continuas..... $M=wL^2/10$

$w$=carga por unidad de luz; L=luz, **JC.**

**182.** En las luces continuas, provéase, en los soportes, para el momento negativo=.8 del momento positivo en el centro de una luz simplemente apoyada. El momento positivo en el centro de la luz contínua, puede calcularse=al momento negativo en el apoyo, **Ms.**

### Pruebas.

**183.** El comisionado ó inspector de edificios puede exigir las pruebas de los materiales antes ó después de ser empleados en los edificios, **Ms.** El contratista debe estar preparado para hacer pruebas de carga en cualquier parte del edificio dentro de un tiempo racional después de la erección y con tanta frecuencia como lo requiera el ingeniero, **Ch, Ph, Mh, Un.** Las pruebas deben demostrar que la construcción resistirá cargas como sigue :

carga=2 × la suma de las cargas viva y muerta presupuestas, **Ch;**
carga=2 × la carga viva presupuesta, **Ph;**
carga=3 × la carga presupuesta, **Mh.**

**184.** La construcción puede considerarse como una parte de la prueba de carga, **Ch.**

**185.** Cada prueba de carga deberá cubrir 2 ó más tram s, permaneciendo en un lugar no menos de 24 horas, **Ch.**

**186.** La deflección de las planchas de no más de $\frac{\text{luz}}{800}$.

La deflección de las vigas armadas $>\frac{\text{la luz}}{800}\times$ la relación entre el espesor de la losa ó plancha y el espesor de la viga, **Ch.**

**187.** La prueba á 45 días después de terminar.

Carga=1.5 × la carga viva + 1.5 × la carga muerta del área terminada.
Deflección $>$ .001 × el largo de la pieza, **Ci, b.**

## ACERAS DE CONCRETO

### Resumen de especificaciones.

Adoptado por

### La Asociación Nacional de los consumidores de cemento.

Filadelfia, enero, 1908.

**1. Cemento** Portland que llene las condiciones de la A. S. T. M., adoptada en enero, 1906. Véase pág. 1278.

**2. Arena.** Que pase el cernidor n.º 4. Puede contener $>$ 5% de marga y arcilla, éstas no envuelven los granos de arena.

$<$ 60% de la arena que pase por el cedazo n.º 10, ó
35% que pase los cedazos n.ºs 10, 20, 3[illegible], 40,
y el resto se quede en los n.ºs 20, 30, 40, 50.
$>$ 20% de la arena que pase el cedazo n.º 50, ó
70% que passe los n.ºs 10, 20,
y el resto se quede en los n.ºs 40, 50 respectivamente.

**3. Cerniduras** de piedra triturada, como se indica más abajo, y que llenen los requisitos para la arena, se pueden sustituir en lugar de la arena.

**4. Agregado. Piedra triturada**, de roca limpia, buena, dura, cernida seca por mallas de 19 mm, que la retenga la malla de 6 mm.

**5. Granzón**, limpio, duro que varíe entre el retenido por la malla de 6 mm y el que pasa por la de 19 mm.

**6. Granzón sin cernir**, limpio, duro. Que no tenga partículas mayores de 6 mm. La proporción de las partículas finas y gruesas debe obedecer á los requisitos que damos más abajo para el concreto.

**7. Agua**, « bastante limpia, libre de aceite, ácido sulfúrico y álcalis fuertes »

## Sub-base.

**8.** La subbase debe **apisonarse muy bien**, quitando las **partes blandas** y reemplazándolas con material duro.

**9. Rellenos** $>$ 30 cm de espesor, que debe compactarse completamente apisonando las capas de $>$ 15 cm de espesor, y « deben tener una inclinación de $<$ 1 : 1.5. » « La parte superior de todos los rellenos debe prolongarse $<$ 30 cm más allá de la acera. »

**10.** « Mientras se compacta la subbase debe **mojársela completamente** manteniéndola así hasta depositar el concreto. »

## Base.

**11. Vacíos.** El cemento debe rellenar los vacíos de la arena en $<$ 5%.

**12.** El mortero debe rellenar los vacíos del agregado en $<$ 10%. Proporciones 1 : $>$ 3 arena y agregado.

**13.** Cuando los vacíos no están determinados, 1 : 3 arena ó cerniduras : 5 piedra ó granzón. « Un saco de cemento de 42.5 kg se supone que ocupa un volumen de 28 litros. »

## Mezcla.

**14. Á mano.** La arena se extiende pareja sobre una plataforma horizontal impermeable, el cemento se esparce sobre la arena. Mézclase seco hasta que tenga un color uniforme. Se riega el agua y revuelve la masa hasta que tenga una consistencia homogénea y uniforme. Se añade el agregado empapapado y se mezcla todo hasta que el agregado esté completamente cubierto de mortero.

**15. Á mano. Con granzón sin cernir.** El cemento y el granzón se « mezclan secos hasta que no se vean vetas de cemento ». Se le riega el agua y se mezcla. El mortero debe ser igual al que se ha especificado más arriba.

**16.** El agua puede añadirse mientras se está mezclando, pero el concreto debe revolverse $<$ una vez inmediatamente después.

**17. La mezcla por máquina** puede aceptarse cuando se obtiene por ella un concreto equivalente al que se especifica más arriba.

**18. Se prohibe la retemplada.**

## Declive

**19. El declive de la acera** $<$ suficiente para el desague $>$ $^1/_{50}$, « excepto donde esta inclinación sea paralela al largo de la acera ».

## Armaduras.

**20. Madera de construcción**, limpia, libre de torceduras, $<$ 4 cm de espesor.

**21. Los bordes superiores deben conformarse** al declive definitivo de la acera.

**22. Armaduras transversales.** « En cada división de bloque se pondrán armaduras transversales en todo el ancho de la acera y en ángulo recto con el lado de la armadura », excepto como se dice en el § 23.

**23. Juntas de dilatación.** Una tira de metal, de separación de 12 mm, que reemplace la armadura transversal $<$ una vez en cada 15 m. « Cuando la acera esté bastante dura, se quitará esta tira de división llenando la junta con material adecuado antes de abrir la acera al tráfico. Se drpondrán juntas de esta especie cuando la nueva acera se empata con aceras de piedra artificial, á curvas ú otras. »

**24. « Todas las armaduras deben mojarse completamente** antes de depositar ningún material contra ellas. »

**25. Dimensiones de los bloques.**

| Tamaños en centímetros..... | 15×15 | 12·5×12.5 | 11×11 | 10×10 | 7.5×7.5 |
|---|---|---|---|---|---|
| Espesor (centims) : | | | | | |
| En los barrios de tráfico..... | 15 | 14 | 12.5 | 10 | ... |
| En los barrios de habitación.... | 15 | 12.5 | ... | 10 | 7.5 |

En las aceras de los barrios de habitaciones los bordes pueden ser 25% más delgados que el centro, mínimum = 7.5 cm.

**26. El hierro de separación** > 15 cm de ancho, 6 mm de espesor. La ranura llega hasta la subbase; la ranura se llena de arena seca antes de extender la capa superior; la capa superior se corta hasta la arena después de emparejar y alisar con la cuchara.

## Colocación.

**27.** El concreto se llevará á las armaduras en carretillas impermeables. El concreto no debe rebosarlas. Las carretillas no deben pasar sobre el concreto colocado recientemente.

**28.** El concreto debe depositarse dentro de una hora después de la mezcla, extendiéndolo parejo, y apisonándolo hasta que el agua fluya á la superficie.

## Protección.

**29.** Los trabajadores no deben caminar sobre el concreto acabado de colocar.

**30.** La arena ó polvo que se reuna en la base, se debe « quitar con cuidado antes de aplicar la superficie que va á sufrir el tráfico ».

## Superficie de tráfico.

**31.** Espesor mínimo, 2 cm.

**32.** « Mortero, 1 : 2 de arena ó cerniduras, mezcladas como para la base, pero bastante mojadas para que no haya que apisonarlas para que puedan aplanarse con barras de filo recto. « Se echará una capa de mortero delgada y se alisará sobre la base, antes de extender la superficie de tráfico. »

El mortero se debe extender en la base dentro de 30 minutos después de mezclado, alisándolo dentro de 50 minutos.

**33. Marcas.** « Después de haber casi terminado la superficie, se harán las marcas de los bloques directamente encima de las juntas de la base, con un hierro que corte hasta la base y separe completamente las superficies de tráfico de los bloques adyacentes. »

**34. Orillas de la superficie,** se redondean con un radio < 6 mm.

**35.** « Cuando estén parcialmente fraguadas, las superficies se **alisarán** con **la cuchara.** »

**36.** En los declives > 5% se **hace áspera** la superficie con instrumento adecuado « ó incrustando arena gruesa en la superficie ».

**37.** Se emplearán únicamente **colores minerales,** y éstos se **incorporarán** al mortero de toda la superficie de tráfico.

## Capa de una sola pega.

**38. Proporciones,** 1 : 2 de arena : 4 granzón ó piedra triturada. **Los bloques se separan** como en el trabajo de doble capa. El concreto debe **compactarse** firmemente **apisonándolo, encerrándolo y alisándolo** dentro de los bordes de la armadura. « Después, con un hierro adecuado, se comprimirán las partículas más gruesas del concreto á la profundidad necesaria de modo que quede lisa como en el trabajo de doble capa. »

## Protección.

**39** Después de terminada se conservará la acera **húmeda y protegida** contra el tráfico y los elementos durante tres días, por lo menos. Las armaduras se quitarán con gran cuidado, y al quitarlas se amontonará **tierra contra la orilla de la acera.** »

## Declive adyacente á la acera.

**40.** En la orilla de la acera 4 cm, por debajo de la acera se hará un declive < $^1/_{50}$. En el lado de las habitaciones « se le dará al suelo un declive hacia atrás < 60 cm pero no más bajo que la acera.

## BLOQUES DE CONCRETO

**1. Puerto de Búfalo.** Bloques de 1.80 m de largo, como 1.2 m en cuadro, como 2.5 m cúb, hechos en moldes de madera. ½ barril de Portland, 70 lit de arena, 212 lit de guijarros, 212 lit de piedra quebrada, para hacer una capa de concreto, en molde, como de 15 cm de espesor. Las caras de 15 cm de espesor de los bloques del tajamar que da al lago, se hicieron del mejor material. El frente se colocó primero; el respaldo antes de fraguar éste. (Emile Low, A. S. C. E., Trans., junio '04, vol. LII, pág. 96.)

**2. Tajamar de Zeebrugge,** Bélgica. Bloques de 25 metros de largo. 9 metros de ancho, 8.75 metros de alto, como 2,000 metros cúbicos, 4,500 toneladas cada uno. La capa exterior de concreto, con un corte inferior, de tres compartimentos, se hicieron en una armadura de hierro y se llevaron en balsas á su lugar, se colocaron entre las guías hundiendo últimamente el bloque; se undió al entrarle el agua, y se rellenó con concreto, 1 de cemento : 2.5 de arena : 6.1 de pórfiro quebrado, por medio de cestones de 10 metros cúbicos. La medida superior, rica en cemento, se colocó sobre el agua en la marea baja. La punta que de hacia el mar se protegió inmediatamente con ripios de piedra.

La superstructura de bloques de 55 toneladas colocados sobre el nivel del agua, y sobre ellos bloques de concreto formados en el lugar.

**3. Moldes para bloques monolíticos bajo el agua, aislados, de concreto,** de 110 á 166 m cúbicos, que forman la pila de la sección transversal de forma trapezoidal. Los moldes son cajas sin fondo, de sección transversal compuesta de dos lados y dos piezas extremas, sujetas por traviesas de torniquete de 38 mm que obran como vigas del lado afuera del molde. Las traviesas tienen, en cada extremo, anillos en que se introducen tornillos-cuñas al tiempo de la erección. Para quitar los moldes se sacan los tornillos destornillando una tuerca en traviesas que forman parte integral de los tornillos-cuñas. Esto, suelta el tornillo de los anillos de las traviesas y deja libre las paredes del molde, que las recoge el mecánico, juntándolas para colocarlas otra vez. Peso del molde, 40 toneladas. Tiempo que se necesita para quitar el molde del bloque y rearmarlo para volverlo á erigir, de 45 á 60 minutos. La flotación de la madera se vence con lastres de hierro. Se colocaron primero bloques alternados. En los bloques intermedios se usaron solamente las piezas de los lados de un molde. Éstas se sujetan en su lugar con su inclinación requerida, por medio de seis travielias de torniquete, que pasa por una caja hueca de planchas de 2.5 cm, y que obra como puntal. (Muelle del Sur, en Superior Entry, Wisconsin, Informe de Clarenee Coleman, ingeniero asistente, Informe del ingeniero en jefe, U. S. A., 1904, parte IV, p. 3781.)

**4. Las clavijas de grapas** deberán ponerse en los bloques donde sea posible, y de tal manera que « no causen exceso de presión en el concreto, especialmente en la cara del concreto ó cerca de los ángulos del bloque ». Las clavijas y los ganchos se pueden poner en los bloques frescos. Usense bloques de madera y cojines de trapos para voltear los bloques, de otra manera se dañarán las esquinas.

**5. Posición para el moldeo.** Los bloques deben moldearse con la cara más importante hacia abajo, estando las caras visibles tan verticales como sea posible, y la parte de atrás del bloque hacia arriba, de manera que la lechosidad, etc., que salga aparezca en la superficie.

## BLOQUES HUECOS DE CONCRETO PARA CONSTRUCCIONES

### Resumen de las especificaciones.

Adoptado por

**La Asociación Nacional de los consumidores de cemento,**

Filadelfia, enero, 1908.

**1. Cemento** Portland que reuna las condiciones de la A. S. T. M., adoptadas enero, 1906. Véase pág. 1278.

**2. Arena,** silícica, limpia, granosa, que pase el cedazo de 6 mm.

**3. Agregado,** piedra quebrada limpia, libre de polvo, ó granzón limpio cernido. que pase el cedazo de malla de 20 mm, retenido en el de 6 mm.

**4. Unidad de medida** para el cemento. Barril = 172 kg netos, el litro = 1.60 kg. El cemento se mide en el embalaje original ó se pesa, no se mide por volumen suelto.

**5. Proporciones.** Para las paredes exteriores descubiertas ó muros de apoyo :
(*a*) Hechos en máquina. Medio húmedo, 1 : > 3 de arena : > 4 de agregado.
(*b*) Concreto aguado (trepidando ó fluyente) hecho en moldes separados dejándolo endurecerse en ellos, 1 : > 3 de arena : > 5 de agregado.
Si se omite la piedra, se podrá aumentar la proporción de arena si las pruebas no indican aumento en los vacíos ó en la absorción ó ninguna pérdida de la resistencia.

**6. Agua suficiente** para completar la cristalización del cemento.

**7. Mezcla.** « La mezcla estricta y completa es de la mayor importancia. »
(*a*) A mano. El cemento y la arena se mezclan secos. El agua se añade despacio y se revuelve. El agregado húmedo se extiende sobre la mezcla, ó la mezcla sobre el agregado y se mezcla.
(*b*) Se prefiere con máquina. El cemento y la arena, ó cemento, arena y agregado, se mezclan secos. Se añade el agua y se revuelve para unirlos. En el concreto mojado, « se puede variar este procedimiento con el consentimiento de la oficina, etc. ».

**8. Moldes.** La parte superior de los bloques apisonados, y después de nives lados, se « alisará con la cuchara ó de otra manera para obtener densidad y ángulos rectos y agudos ».

**9. Protección.** Después de moldeados, los bloques se « protegerán cuidadosamente de las corrientes de aire, el sol, el calor seco ó la helada durante 5 días por lo menos », dándoles mayor humedad durante ese tiempo « y después de cuando en cuando hasta que estén listos para el uso ».

**10. Edad mínima** antes de usarlos. 1 : 3 de arena, 3 semanas; 1 : 2 de arena, 2 semanas, « con consentimiento especial de la oficina, etc. »; bloques especiales para rematar el trabajo, 7 días « con consentimiento especial de la oficina, etc. ».

**11. Marcas.** Todos los bloques deben marcarse con el nombre ó la marca del fabricante, día, mes y año de la hechura y las proporciones, « 1 : 2 : 3 », etc.

**12. Mortero.** « En todos los muros en que se empleen los bloques, se pegarán éstos con mortero de cemento Portland.

**13. La carga máxima,** incluyendo el peso de la pared, 88 toneladas por metro cuadrado del área de los bloques.

**14. Espesor de los muros.** Los muros de apoyo « pueden tener 10% menos de lo que exige la ley para muros de ladrillo ». En las paredes de división ó tabiques lo mismo que en las baldosas huecas ó de terracotta ó de bloques de yeso.

**15. Disminución de espesor.** « Cuando las paredes disminuyen en espesor, la última hilada del muro más grueso deberá presentar un apoyo suficiente y sólido para las armazones ó muros de la serie de bloques de arriba. »

**16. Debajo de las vigas,** los bloques deben hacese sólidos en < 20 cm de la cara interior. Si la carga concentrada, W, en el bloque, es > 2 toneladas, ésta se aplica á los bloques que soportan la viga, etc.; si W, > 5 toneladas, se aplica á los bloques de < 3 hiladas de abajo, y á una distancia de < 45 cm á cada lado de la viga, etc.

**17. En los muros de división,** se harán los bloques sólidos.

**18. Sujeción.** « Cuando los muros se hacen enteramente de bloques de concreto, y que dichos bloques no tengan el mismo ancho que el muro, en cada 5.ª hilada se prolongará por todo el ancho del muro, formando una sujeción segura, cuando no estén suficientemente sujetos de otra manera. »

**19. Las caras de los bloques,** en el respaldo de ladrillo, « deben estar sujetas fuertemente al ladrillo con dientes que se introduzcan 10 cm en la obra de ladrillo, considerando cada cuarta hilera como muro de cabeza; ningún respaldo de ladrillos deberá ser de menos de 20 cm.

**20. Espesor del alma ó armazón** del bloque (en los muros de apoyo) < .25 × por la altura del bloque.

**21. Espacio hueco.** En los muros de apoyo el percentaje mínimo de espacio hueco :

| Edificios de | 1.º | 2.º | 3.º | 4.º | 5.º | 6.º pisos. |
|---|---|---|---|---|---|---|
| 1 y 2 pisos..... | 33 | 33 | | | | |
| 3 y 4 — ..... | 25 | 33 | 33 | 33 | | |
| 5 y 6 — ..... | 20 | 25 | 25 | 33 | 33 | 33 |

**22. Los quicios y dinteles** deben « reforzarse con barras de hierro ó acero de un modo que satisfaga á la oficina, etc. ». Cuando la luz sea > 1.35 m, el quicio « deberá descansar sobre un bloque sólido en < 20 cm de distancia de la

cara próxima á la abertura y en $\leq$ 3 hileras por debajo de la parte inferior de dintel ».

**23.** Antes de usar los materiales se **hará una solicitud** á la oficina ó jefe del departamento del ramo, dando « una descripción de ellos y un bosquejo breve de su manufactura y las proporciones que se van á usar », con « el nombre de la firma ó corporación, y los empleados responsables de ellos », dando inmediata cuenta de los cambios que se tengan que hacer.

**24. El certificado de aprobación** permanecerá en vigor $\geq$ 4 meses, « á menos que se deposite en la Oficina de inspección de edificios, lo menos una vez cada cuatro meses, un certificado de un laboratorio de pruebas físicas, competente, que indique que el término medio de $\leq$ 3 pruebas de compresión y $\leq$ 3 pruebas transversales llenan los requisitos; « dichas muestras se elegirán (por un inspector de edificios ó por el laboratorio) de los bloques que se vayan á colocar en la construcción ».

**25. Prueba preliminar.** El fabricante someterá el producto á las pruebas requeridas, depositando un certificado de un laboratorio competente de pruebas, que dé los detalles de las pruebas que se hayan hecho. Los resultados de todas las pruebas, satisfactorios ó no, se depositarán en la oficina, expuestos á la inspección, pero no de obligatoria publicación.

**26. Pruebas adicionales.** El fabricante, ó el que los usa, ó ambos, « harán en cualquier tiempo tales pruebas de los cementos que se hayan empleado para hacer estos bloques, ó las mismas pruebas posteriores con los bloques terminados, ó con cada uno de ellos, por su propia cuenta, y bajo la inspección de la oficina de inspección de edificios, como el jefe de dicha oficina lo exija ».

El no resistir estas pruebas, implica la revocación inmediata del certificado concedido al fabricante.

**27. Requisitos para las pruebas.** Los bloques deben someterse á pruebas transversales, de compresión y de absorción, « y podrán someterse á pruebas de congelación y de fuego ». Las pruebas de congelación y de fuego no serán por cuenta del fabricante.

**28. Las pruebas de aprobación** se harán por cuenta del solicitante.

**29.** No se elegirán **menos de 12 muestras** por la oficina, etc.

**30.** « Las muestras deben representar el **producto comercial corriente,** del tamaño regular y la forma que se usen en la construcción. Las muestras se probarán tan pronto como lo desee el solicitante », pero $\geq$ 60 días después de fabricadas.

**31. Los bloques que fallen en las pruebas,** se marcarán « condenados » por el fabricante ó el que los usa, y se destruirán.

**32.** « **Las pruebas se harán en series** de 3 por lo menos, exceptuando las pruebas de fuego en que series de 2 (4 muestras) son suficientes. »

**33.** « **Las medias muestras** se podrán usar para las pruebas de fuego, congelación y trituración. Las muestras restantes se conservarán en reserva para el caso en que se requieran pruebas duplicadas ó confirmatorias. »

**34.** « **Todas las muestras deben marcarse** para su identificación y comparación. »

**35. Pruebas transversales.** La muestra (de tamaño completo) se colocará de plano en soportes de filos redondeados paralelos, á 18 cm de separación. Se aplica la carga, en la mitad de la distancia, entre los soportes, por entre los filos redondeados.

Coeficiente de ruptura $= 3WL / 2d^2$; en que W=la carga en kg; L=la luz en dcm; $b$=ancho del bloque en cm; $d$=espesor del bloque, en cm. « No se deberá hacer concesión... por los espacios huecos. » A los 28 días el módulo de ruptura será por término medio de 10.5 kg/cm cuad, mínimo 7.

**36. Prueba de compresión.** « Las muestras se deben cortar de los bloques de manera que contengan una sección completa de alma. Se debe medir la muestra con cuidado, colocándola después en un lecho de yeso, para obtener un soporte uniforme en la máquina de prueba, y luego triturarla. La carga total de ruptura se divide entonces por el área comprimida, sin deducir los espacios huecos; el área se considerará como el producto del ancho por el largo. »

**37. Esfuerzo máximo de compresión** á los 28 días, promedio 70 kg/cm cuad mínimo 49.

**38. En las paredes ó muros de apoyo,** mínima 70 kg/cm cuad. No se hace deducción por los espacios huecos.

**39. Absorción.** La muestra se seca hasta el peso constante á 100° C. Se pesa, se coloca en agua con la cara hacia abajo, se sumerge á $\leq$ 5 cm. Se pesa á los

30 minutos, las 4 horas, las 48 horas, y se vuelve á colocar en el agua inmediatamente después de cada pesada. Al fin de las 48 horas se determinará la resistencia de compresión de la muestra mojada, según el § 36.

$$\text{Absorción} = \frac{\text{peso del agua absorbida}}{\text{peso del bloque seco}}. \text{ Promedio} > .15 \text{ máxima, } .22.$$

**40. La reducción de la resistencia á la compresión**, por la absorción, $> \frac{1}{3}$ *.

**41. Prueba de congelación.** Se sumerge la muestra, como en el § 39, durante 4 horas, y se pesa. Se somete á $<$ — 10° C, durante $<$ 12 horas. 1 hora en agua de $>$ 67° C. Se repite la operación diez veces. Se toma el peso todavía mojada de la última deshelada. « Y se determina su resistencia á la trituración » como en el § 36.

**42 Pérdida de peso** máxima 10%; **pérdida de resistencia**, máxima $\frac{1}{4}$ *.

**43. Prueba de fuego.** Se colocan dos muestras frías en el horno. Se eleva la temperatura gradualmente á 927° C. Se mantiene por 30 minutos. Una de las muestras se sumerge en agua como de 10° á 16° C. La otra muestra se deja enfriar gradualmente al aire. « El material no debe desintegrarse. »

**44. El ladrillo de cemento**, como sustituto del ladrillo de greda. 1 : $>$ 4 de arena limpia aguda; ó 1 : $>$ 3 de piedra quebrada ó granzón que pase el cedazo de 12 mm y se detenga en el de 6 mm. En otros respectos los ladrillos de cemento deben llenar los requisitos de los bloques huecos de concreto.

---

* « Excepto que cuando la cifra inferior esté todavía sobre 70 kg/cm cuad, se podrá despreciar la pérdida de resistencia.

# COSTO *

**1.** Los siguientes datos respecto á los precios y costo se han completado con los informes de construcciones recientes ejecutadas por individuos que se tienen por peritos en el arte, y calculando la obra de mano con los jornales de costumbre. Ellos dan solamente los cálculos aproximados de lo que se puede esperar en circunstancias ordinarias. El costo de los materiales, transporte y especialmente de la obra de mano, varía con el tiempo y la localidad.

**2.** No sólo varía el precio de la obra de mano por hora, sino que la cantidad misma de trabajo ejecutado en un tiempo dado, varía mucho más. Una cuadrilla bien organizada, presidida por un vigilante competente, produce ordinariamente de dos á cuatro veces lo que una cuadrilla cualquiera. Aun los buenos trabajadores dejan decaer su labor, con frecuencia, al 75% de lo que se podría esperar de ellos; los trabajadores sin interés dan solamente del 30 al 20%. Los sistemas del pago, el carácter del superintendente, y el modo de distribuir y manejar el trabajo, son todos de gran importancia, y un trabajador sin práctica ó que no esté familiarizado con las obras de concreto encontrará probablemente dificultad en conservar el costo total dentro del doble de lo que damos.

**3.** Las **principales partidas**, que forman el costo del concreto (simple y armado), pueden clasificarse como sigue:

Materiales: cemento, arena, granzón, piedra, armazón.
Transporte al almacén; acarreos, fletes.
Almacenaje.
Cernidura, lavado.
Mezcla, carga y transporte al mezclador, máquina de mezclar y fuerza, obra de mano y depreciación relacionada con ella, aparatos auxiliares, tales como: tablas para mezclar, carretillas, palas, etc., y el transporte del concreto á los moldes, armaduras, etc.
Armaduras; erección, cambios de lugar, depreciación, material, mano de obra.
Colocación; vaciado, extensión y apisonado.
Acabado; enlucido, acepillado, etc.
Inspección y superintendencia.
Planta (además del mezclador y las armaduras); interés, depreciación, refracciones, aseguro.

## Costo de los materiales.

**4.** El costo de cualquier material, *por metros cúbicos* de concreto, varía mucho en los diferentes casos, debido á la gran variación en los percentajes que se emplean en las diferentes especies de concreto, y por consiguiente sólo se pueden dar aproximadamente entre límites muy amplios.

**5.** Estimando aproximadamente, el **costo total**, para los **materiales** solamente, puede caer entre $3.25 y $9.75 el metro cúbico de concreto. El término medio será probablemente de $5.20 ó un poco más, sin incluir la armazón **.

**6. Cemento.** Por metro cúbico de concreto, entre $1.95 y $5.20; $2.60 y $3.90 son los límites más usados. Varían principalmente por el grado de cemento y la riqueza de la mezcla **.

**7. Arena.** Por metro cúbico de concreto, entre 19 centavos y $1.36 ordinaria-

---

* *N. del T.* — Aunque el costo de materiales, mano de obra, etc., varía mucho, y con multitud de circunstancias, trae el autor en estas páginas tanto dato importante en la práctica, que no hemos vacilado en dejar el capítulo. Además, casi siempre podemos dar el precio que él supone (en una lista de precios cuya inserción no creemos necesaria en su totalidad) para la unidad del material ó de la mano de obra, y así se hace muy fácil calcular, aunque sea aproximadamente, los costos correspondientes en otras localidades con diversos jornales, etc. Es claro que todo lo hemos convertido al sistema métrico.

** *N. del T.* — El autor supone los precios siguientes (en dólares): **Cemento**: americanos, 1.40 á 4.60; alemanes, 2.25 á 3.00 (barriles de 180 kg brutos). Natural Rosendale (barriles de 136 k), .85 á 1 dólar. Por cada 1,000 ladrillos se gastan de 1.5 á 3 dólars. **Cal**, .60 á .90 los 100 kg. Se gasta de 1 á 1.50 dólars por 1,000 ladrillos. **Yeso**, 1.5 á 2 dólars por barril. **Piedras**, .28 á .66 por m cúb; piedra común de construcción, 1.30 á 7.00 por m cúb. **Granito**, 20 á 60 por m cúb. **Asfalto**, 2 á 5 por tonelada.

mente. Varía según la clase, la distancia del depósito, el monopolio natural, y la proporción que se use en la mezcla.

**8. Granzón.** En la cantera, excluyendo la cernidura, carga y acarreo, de 25 á 75 centavos por carro; los afectan principalmente la calidad y el monopolio natural.

**9. Piedra.** Precio medio de la piedra, quebrada al tamaño que se requiera, en la cantera, excluyendo el acarreo, cerca de $1.30 ó $1.95 por metro cúbico de piedra. Por metro cúbico de concreto se gasta entre 65 centavos y $1.30. Los afectan principalmente la calidad, distancia de la cantera, el monopolio natural y la proporción de la mezcla.

**10. Armazón.** El costo varía con el diseño y el tipo que se emplea *.

Barras lisas, lotes de 50 toneladas, en la fábrica, centavos por kg aproximadamente: < ¾", 3 cs; < ½", 3½ cs; < ⅜", 4 cs; < ¼", 4½ cs.

Barras torcidas Ramsome, como ²/₇ más de centavo por kg.

Otras barras deformadas, 1½ á ²/₃ más de centavo por kg.

**11.** El percentaje en la armazón varía ordinariamente de ½% á 1½%, más ó menos, de la sección transversal de la viga ó losa.

## Costo del transporte al almacén.

**12. Flete.** El cemento por ferrocarril. Los fletes varían mucho en las varias localidades, debido con frecuencia solamente á causa de la descriminación arbitraria, variando desde ½ centavo por tonelada-milla á más de 2 centavos; en general de 1 á 2 centavos.

**13.** Por canal. Cargas por lotes de 100 toneladas de 2,000 libras cada una; cemento, 1 á 2 centavos /tonelada-milla, de acuerdo con la distancia; piedra y arena, ¾ á 1½.

**14. Flete costanero.** En lotes de cargas de vagones, .4 á .6 centavos /tonelada-milla, aproximadamente.

## Costo de almacenaje, etc.

**15. Almacenaje.** Ordinariamente, los barriles de cemento se pueden almacenar en hileras de 5 barriles que requiere como ⅛ de m cuad de espacio por barril.

**16. Cernidura.** Costo, á mano, entre 13 y 32 centavos ó más /metro cúbico de material trabajado. Cernidura por máquina, entre 5 y 8 centavos /metro cúbico. Para obtener el costo por metro cúbico de material cernido, multipliquese el costo por metro cúbico por la relación de la cantidad total trabajada á la cantidad aceptada.

**17. Lavado.** El costo del lavado de la arena, granzón y piedra triturada puede ser de 6½ centavos ó más por metro cúbico de material trabajado en lavadores mecánicos que lavan grandes cantidades. En cantidades pequeñas, lavadas bajo condiciones favorables, hasta 52 centavos.

## Costo de la mezcla y colocación.

**18. Mezcla y colocación. Costo total,** excluyendo las armaduras, de $1.30 á $3.25 /m cúb.

**19.** La obra de mano que se requiere, para cantidades bastante grandes, es, por término medio, un hombre por cada 1½ ó 2 metros cúbicos mezclados y colocados por día. En los trabajos pequeños un hombre ejecutará mucho menos.

**20.** El concreto seco cuesta como $1.30 más por metro cúbico para mezclarlo y colocarlo que el concreto mojado. Herman Conrow, Jr., A. S. C. E., Trans., vol. 42, 1899, pág. 124.

**21. Carga.** Se cargan en los carros de 9 á 18 m cúbicos de arena por hombre y por día; 9 parece ser lo usual, pero 18 no es exagerado.

**22. Transporte.** Carga media de piedra quebrada, granzón ó arena.

| | |
|---|---|
| Carretillas de madera..... | =68 litros. |
| — de hierro..... | =53 — |

El costo de transporte por metro cúbico de concreto ordinario es entre 14 y

* Hierro refinado y acero en barras de tamaños ordinarios; ángulos y T, vigas ángulos, placas de formas comunes y acero Bessemer para máquinas, de 2 á 2.66 centavos por kg. Carriles de acero, $28 por tonelada; viejos, $15.

32 centavos, dependiendo en gran parte de la distancia y mérito de los trabajadores.

## Costo de la mezcla.

**23. Mezcla (solamente).** Mucho depende del interés de los trabajadores y del tamaño del mezclador. Varios ejemplos indican costos menores de 13 centavos/metro cúbico, contando la obra de mano solamente, mientras que otros indican, con bastante frecuencia, como 32.5 centavos. Sabin dice : « El costo de la mezcla del concreto en grandes cantidades es rara vez menos de 39 centavos/metro cúbico si se hace concesión por la planta ó instalación. »

**24.** Hasta donde sea posible, el material debe rodar hacia abajo, conservando el mezclador por encima de la obra, si se puede. Si se usa un ascensor para el concreto, su entrada deberá estar por debajo del mezclador. En los trabajos subterráneos ó de cloacas, se puede colocar algunas veces el mezclador debajo del nivel de la calle, pero siempre sobre el nivel de la obra, de modo que no sea necesario levantar el material después de vaciarlo de los carros á la calle. Se pierde mucho si el suministro del cemento en la obra y la demanda del concreto no se conservan casi iguales, ó si las condiciones son tales que los hombres no puedan moverse con libertad.

**25.** Generalmente, no se puede dedicar más de media docena de hombres á un mezclador, de manera que puedan manejarlo con ventaja, medir material, limpiar las plataformas, etc. (además de los que estén ocupados en llenar y traer los materiales al mezclador ó á la obra). El costo, por la obra de mano solamente, no debe ser mucho más de 20 centavos por metro cúbico de concreto, aun con máquinas pequeñas.

**26. Los mezcladores** que den 280 á 1,120 litros de concreto por carga (ó, suponiendo una carga cada 2 minutos, 280 á 1,120 litros por hora), costarán de $500 á $1,000, y necesitarán de 5 á 10 HP. para moverla. Las máquinas movidas á brazo, con una capacidad de 140 litros por carga, como $250.

**27. El costo de montar** un mezclador, y de desmontarlo, incluyendo el acarreo á unas pocas millas, y su depreciación, entre $50 y $100.

Hasta 75 ó 150 m cúbicos de concreto, la mezcla á brazo es ordinariamente más económica que por máquina.

**28.** El costo inicial de una **planta de mezclar á brazo** que la manejen 8 ó 10 hombres, se calcula como sigue :

| | |
|---|---|
| 8 palas de punta cuadrada, tamaño n.º 3..... | $ 10 |
| 3 carretillas de hierro..... | 35 |
| 2 pisones..... | 5 |
| 1 plataforma de mezclar, 4.5 × 4.5 m..... | 10 |
| | $ 60 |

**29. Ejecución.** Cuando el material se entrega prontamente, los mezcladores de carga darán, por término medio, un lote cada 2 ó 3 minutos. Un lote en un minuto es un trabajo muy rápido. Algunas veces se requieren de 4 á 5 minutos. Para las capacidades y fuerza que requieren, véase « Mezcladores », § 26.

**30.** El costo de una planta para mezclar concreto se calcula entre 3 y 5% ó más, del costo de la obra.

**31. La duración de un mezclador,** en condiciones ordinarias, es de 30,000 á 40,000 cargas. De este modo, un mezclador que dé 120 cargas por día, necesitará renovarse al año. Se necesitará un tambor nuevo (generalmente) después de mezclar dos tercios de la cantidad total.

**32. Del mezclador á las armaduras.** El tiempo que se necesita para llenar una carretilla en el mezclador, es como de 10 segundos; para descargar todo el mezclador en una operación, de 15 á 20 segundos.

**33.** La carga media de concreto mezclado en una carretilla es de 42 á 50 litros. Un carro de un caballo carga como ½ m cúbico; de dos, ¾ á 1½ m cúbicos. Para computar los gastos de acarreo, etc., véase el art. 4, pág. 864.

**34** Un hombre puede palear de 7.5 á 10 m cúbicos de concreto en 10 horas por día.

## Costo de las armaduras.

**35** El costo, incluyendo el material y la obra de mano, varía principalmente con el carácter de la obra; las armaduras simples para trabajar en masa, son rela-

tivamente baratas, mientras que las de detalles de muros y pisos de edificios son más costosas, especialmente en el cemento armado.

**36. El material** para las armaduras, entre 13 centavos y $1 por metro cúbico de concreto, y en el lugar.

**37.** La **construcción y erección** solamente, cuestan de **$4 á $10 por 1,000 pies B. M.** (más ó menos 100 m cuad de tabla de 2.5 cm de espesor) en las construcciones más simples; en los edificios, de $10 á $20.

**38.** El costo de las armaduras puede ser de 10 á 50 **por ciento** del costo total del concreto en el lugar; 25 á 35% por las armaduras para trabajo ordinario de concreto armado; 50% ó más para los trabajos de detalles en los edificios.

**39.** El costo, **por metro cuadrado de superficie** (como un lado de una pared), puede computarse mejor para el trabajo que se esté haciendo, dados el valor de la madera y la obra de mano de que se disponga, pero ordinariamente es de .4 á 2 dólares.

**40.** El costo de las armaduras, **por metro cúbico de concreto**, en la construcción de edificios, se calcula entre $3.90 y $13; de $5.20 á $7.80 siendo suficiente para la construcción de pisos, y $6.5 á $9.10 es lo ordinario para las armaduras en los trabajos de concreto armado.

**41. Cambios y depreciación.** En los números que se han dado para el costo de las armaduras, se ha supuesto que el material no se va á usar otra vez. En los trabajos especiales que tengan detalles extraordinarios y difíciles, las armaduras son prácticamente inútiles después que se han usado. Generalmente la madera puede usarse 2 ó 3 veces antes de desecharla. En los edificios grandes, cuyas armaduras se diseñan esmeradamente y que en los detalles son las mismas en todo el edificio, se pueden usar las armaduras hasta seis veces.

**42.** El trabajo de mano para cambiar los moldes no será mucho menos que el de construirlos.

**43.** El costo de la **obra de mano, para colocar** las armaduras, está entre 3 á 4% y 20% del costo del concreto en el lugar.

## Costo de la colocación.

**44.** El costo de la **fabricación** (arcos, armada, etc.) **y colocación de la armazón**, es como de 1 á 3.3 centavos /kg de armazón.

**45. Depósito.** La obra de mano efectiva que se necesita, para el depósito solamente, rara vez llega á más de un hombre para ayudar á descargar los carros, cambiar las canales de descarga, etc., no más de unos pocos centavos por metro cúbico de concreto colocado. En los informes se da de 7 centavos para arriba, pero en esto quizás se incluya el transporte del mezclador á las armaduras.

**46. Esparcimiento y apisonado.** El costo varía mucho con la clase de la obra; siendo tan bajo como de 19 centavos por metro cúbico en los trabajos ordinarios (6.5 centavos si la mezcla está muy húmeda), hasta $1.30 ó más cuando se tiene gran esmero en la colocación, apisonado, compresión, etc. Menos, si el concreto se vacía de los carros ó baldes en grandes cantidades.

**47.** Por el apisonado solamente, de 6 á 19 ó 26 centavos /metro cúbico, rara vez más de 52 centavos.

## Gastos varios.

**48. Inspección y superintendencia**, como se hace generalmente, de 1 á 3% del costo de la obra. En vista de las grandes dificultades que resultan si el trabajo no está bien arreglado ó que los hombres no se mantienen en orden, puede dejar cuenta gastar 5 ó 10% más.

**49. Acabado.** Los datos son muy variables, debido probablemente á la diferencia en los sistemas.

**50.** Lavado con brocha, 3 á 10 centavos /m cuadrado de superficie, con ácido hidroclórico diluído para quitar la eflorescencia, como $2 m cuadrado.

**51.** Preparado á martillo de las superficies, .30 á 2.60 dólares por m cuadrado. Con aparato neumático, menos de 1 centavo. Acabado de las juntas y enlucido á brocha, $2.5 /m cuadrado ó más.

## Costos totales.

**52. Sencillo.** Para el costo total, véase « Masa », etc., § 55.

**53. Concreto seco,** como $1.30 más /metro cúbico que el concreto mojado, debido al trabajo adicional de apisonarlo.

**54. Concreto de granzón**, de $1.20 á $2.60 por m cúb más barato que el concreto de piedra dada la misma proporción entre (arena+piedra) y el cemento, la mayor diferencia se obtiene en mezclas pobres en cemento.

**55. Masa.** Los tajamares, fortificaciones, etc., cuestan entre $6.50 y $9.10/metro cúbico de concreto en el lugar, siendo el término medio $7.80. Los extremos, entre $5.20 y $10.40.

**56. Armazón.** Cuando el trabajo está bien organizado, los edificios de cemento armado pueden construirse desde $13/metro cúbico de concreto en el lugar, pero el término medio general es más cerca de $23.40, aunque algunos constructores calculan en redondo en $35.00 el metro cúbico, pero en muy pocos casos han costado tanto.

**57.** El costo depende principalmente de las armaduras (véase § 36). Si éstas están bien diseñadas de manera que puedan cambiarse fácilmente y que se puedan usar varias veces, el costo es bajo, comparado con los trabajos especiales, en que el refinamiento en el diseño no dejaría cuenta.

**58. Muros de sostenimiento**, los muros de cimientos, los empotramientos, las esclusas, los muelles, etc., varían mucho, debido aparentemente á las dificultades que pueden presentarse en la construcción. Los extremos varían entre $5.20 y $20.80 metro cúbico de concreto en el lugar. Muy á menudo, sin embargo, el precio puede ser de $7.80 y $10.70. En las paredes armadas, de $3.90 á $13 más.

**39. Los arcos** de luz moderada, digamos hasta 9 m en los trabajos de cloacas, etc., de $6.50 á $13 metro cúbico.

**60. Edificios.** El costo puede caer entre $7.80 y $15 por metro cúbico de concreto en el lugar, con término medio de cerca de $10.40 para el sencillo, y de $13 á $19.50 ó $26 para la construcción armada.

**61.** Para cualquier tipo dado de construcción, todas las partes de un edificio (exceptuando los cimientos), como los pisos, paredes, y columnas, cuestan prácticamente lo mismo por metro cúbico.

**62.** Mr. L. C. Wason (E. R., '09, febrero 27, pág. 233) da como **costo de los edificios**:

| | $ por metro cúbico de espacio cerrado. | | | $ por metro cuadrado de piso. | | |
|---|---|---|---|---|---|---|
| | Máximo. | Promedio. | Mínimo. | Máximo. | Promedio. | Mínimo. |

# ENLUCIDOS

El enlucido de las paredes interiores de los edificios, ya sea que se haga sobre listones, ladrillos ó piedra, consiste generalmente en tres capas separadas de mortero. La primera se compone de 1 medida de cal viva para 4 de arena (la que no necesita ser de la clase más pura) y ½ de medida de pelo de buey ó caballo, el cual sirve para aumentar la cohesión del mortero y hacerlo menos capaz de agrietarse. Esta capa es como de 9 á 12 mm de espesor. Se coloca toscamente y se comprime con la llana con suficiente fuerza para que se introduzca perfectamente entre y por detrás de los listones, los cuales, para facilitar la operación, no deben tener entre sí una separación menor de 12 mm. En los edificios rústicos ó en los sótanos, etc., ésta es generalmente la única capa que se usa. Cuando esta primera capa se ha dejado secar ligeramente uno ó más días, según el estado del aire, se araña ó raspa con una astilla de madera puntiaguda, penetrando casi todo su espesor y formando líneas diagonales que se crucen y separadas de 5 á 10 cm. Esto facilita la adherencia de la segunda capa, la que se descascaría si no fuese por esto. Si la primera capa se ha secado demasiado, es conveniente humedecerla un poco al poner la segunda.

La segunda capa tiene de 6 á 10 mm de espesor de la misma argamasa de pelo ú otra materia burda. Antes de que se endurezca se la hace áspera por medio de una escobilla ó algún otro utensilio para que la tercera capa se adhiera mejor.

La tercera capa, como de 12 mm de espesor, no contiene pelo, y para darle una apariencia todavía más blanca y más limpia, se le pone más cal (1 de cal para 2 de arena), y se emplea la arena más pura.

En lugar de estuco la tercera capa puede ser, y lo es generalmente, de una mezcla compuesta de una de yeso en polvo para 2 de cal viva, sin arena. Esta mezcla se hace de más fácil manejo, pero no es tan buena como el encalado para paredes que han de pintarse al óleo. El yeso acelera el endurecimiento.

Cualquiera de estas terceras capas se pule ó alisa más ó menos, según que se vaya á empapelar, á pintar ó dejar descubierta. Los instrumentos para pulir se reducen á la *llana*, la regla de alisar y la brocha de agua (una brocha de mango corto con que se humedece la parte de la superficie que se trabaja á fin de pulimentarla más fácilmente). Para un pulido más fino se usa una regla hecha de corcho. La pieza lisa de madera, como de .25 á .30 m en cuadro, que tiene un mango por debajo para agarrarla y en la que pone el obrero la argamasa, para extenderla con la llana en la pared, se llama *gamella* (*hawk*, Ponce de León).

Mientras más se repase con la brocha de agua y la llana cada capa, más firme y más fuerte quedará. A menudo sólo se hacen enlucidos con dos capas en los cuartos inferiores ó donde no se requiere muy buena apariencia. La primera es de argamasa con pelo ú otra materia áspera. Ésta se araña con la escobilla y luego se cubre con la capa final de mortero más fino. Si esta última es casi toda de cal ó con muy poca arena para trabajarla más fácilmente, se llama *encalado* ó *enlucido ligero*. Sin ninguna arena se llama *enlucido fino*. Ninguno de los dos es tan bueno como el encalado si se va á empapelar la pared.

Cuando es este el caso, puede ponérsele á la tercera capa un poco de pelo para darle más consistencia; pero esto no es absolutamente necesario.

(*Obs. del T.* — Entre nosotros se empapela con buen éxito aplicando el papel directamente sobre la capa del encalado, que como es una capa formada de una mezcla de iguales partes de cal y arena fina, si se deja sin alisar mucho la superficie, al fraguar la mezcla forma ésta un solo cuerpo de bastante cohesión, á cuyas asperezas se adhiere el papel. Siempre se evita, ó mejor dicho, nunca se empapela sobre la capa de lechada, pues siendo ésta un agua de cal casi pura, al secar se desprende la cal con el papel no obstante el mucílago que se le agregue para darle consistencia.)

Se puede producir muy buen efecto en las estaciones de ferrocarril, iglesias, etc., con sólo dos capas en las cuales se emplea cascajo fino, cernido, en lugar de arena. Cuando se le trazan estrías ó líneas regulares, presenta el aspecto de una piedra arenisca color de ante muy agradable á la vista.

Cuando se compre pelo para estucar debe tenerse cuidado de que no sea de cueros

salados, pues la sal hará la pared húmeda. Por esta misma razón no debe emplearse la arena del mar. Es casi imposible quitarle la sal por completo.

Si se pretende enlucir ó encalar una pared de ladrillos, las juntas del mortero deben dejarse bien ásperas para que la mezcla se adhiera. Si se aplica á paredes lisas sin raspar antes el mortero hasta una profundidad de cerca de 2½ cm, es muy fácil que se caiga, especialmente en las paredes exteriores, como se puede ver diariamente en cualquiera de nuestras ciudades. Como el escarbar ó descubrir las juntas de los ladrillos es fastidioso y costoso, sería mejor usar pintura en lugar del enlucido. A las paredes debe quitárseles todo polvo y humedecerlas un poco á proporción que se pone el enlucido.

Para imitar el granito en las paredes exteriores se procede así: Después que la segunda capa se seca se le da una mano de lechada con un pequeño tinte de tierra siena ú ocre, etc. Después que ésta se seca, y en caso de que aparezca muy obscura ó demasiado clara, puede aplicársele otra con más ó menos colorido. Finalmente, con una brocha chata, se le da una rociada de agua de cal y negro mineral, para imitar las manchas negras del granito. Por este simple medio, un obrero hábil puede producir excelentes imitaciones. Las juntas horizontales y verticales de la imitación de mampostería, pueden rayarse con una brocha pequeña usando la misma solución negra y una regla larga recta.

Las superficies toscas de todas las paredes son más ó menos onduladas y fuera de línea y al aparejador le es imposible rectificarlas con exactitud al ojo, como se ve en casi todas las casas. Hasta en las que se titulan de primer orden, un ojo experimentado puede generalmente descubrir ondulaciones de mal efecto en las superficies enlucidas ó encaladas.

Para impedir esto se ha apelado al procedimiento de **la plantilla**. Las plantillas son una especie de guías formadas por la aplicación á la primera capa basta del aljorozado, cuando está medio seca, de bandas horizontales de la mezcla de enlucir como de 20 cm de ancho y de 2 á 4 pies (.60 á 1.20 m) de separación alrededor de todo el cuarto. Éstas se hacen de manera que sobresalgan de la primera capa hasta la superficie de la segunda, y mientras están blandas se hacen con cuidado perfectamente derechas y paralelas, por medio de la plomada, etc. Cuando se secan, se coloca la segunda capa, rellenando los espacios anchos horizontales entre ellas, y se hace fácilmente una superficie plana que corresponde con la de las plantillas ó guías por medio de largas reglas rectas que se extienden á la vez sobre dos ó más de éstas.

**Un día de trabajo en enlucido.** Un albañil ayudado por uno ó dos obreros que le mezclen el mortero y se lo tengan á la mano, puede hacer de 80 á 160 m cuad de la primera capa por día; como ⅔ de dicha cantidad de la segunda, y como la mitad de la tercera, que requiere más cuidado. La cantidad que haga dependerá del número de ángulos, tamaño de las piezas ó de que trabaje en techos ó en paredes, etc.

**Presupuesto del general Gillmore sobre el costo del encalado de 80 m cuad** con 2 ó 3 capas. Salario ordinario de un obrero, 1 dólar por día.

| Material. | Tres capas. Obra acabada. | | Dos capas. Enlucido con poca arena | |
|---|---|---|---|---|
| Cal viva | 4 pipas. | $ 4.00 | 3½ pipas. | $ 3.33 |
| — para trabajo fino | ⅔ pipa. | .85 | | |
| Yeso de París | ½ pipa. | .70 | | |
| Listones | 2,000. | 4.00 | 2,000. | 4.00 |
| Pelo | 145 litros. | .80 | 109 litros. | .60 |
| Arena común | 7 cargas. | 2.00 | 6 cargas. | 1.80 |
| Arena blanca | 91 litros. | .25 | | |
| Clavos | 13 lbs. | .90 | 13 lbs. | .90 |
| Obra de mano de albañil | 4 días. | 7.00 | 3½ días. | 6.12 |
| Obreros | 3 días. | 3.00 | 2 días. | 2.00 |
| Acarreo | ..... | 2.00 | ..... | 1.20 |
| Costo de 80 m cuad | ..... | $25.50 | ..... | $19.95 |

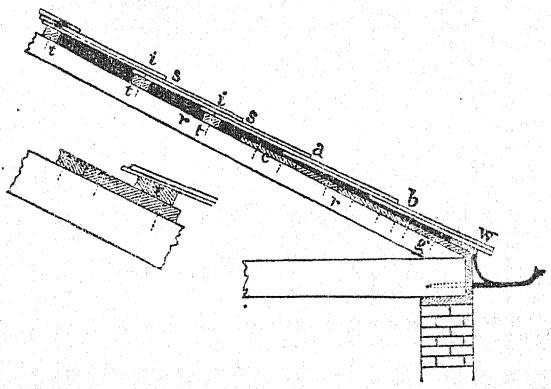
Esto alcanza á 32 cent por m cuad para tres capas y como 25 cent para dos capas.

**Los listones para enlucidos** son generalmente de pino blanco ó amarillo como de 1 á 1.20 metros; tienen como 4 cm de ancho por 3 cm de grueso. Se clavan

horizontalmente á un poco más de 1 cm de distancia. Los postes verticales de los tabiques se colocan á la distancia necesaria (generalmente á unos 40 cm de centro á centro) para que los extremos de los listones se puedan clavar en ellos. Los listones se venden en atados de 1,000, que, colocados como se ha dicho, cubren 62 m cuad. Se pueden obtener aserrados, de cualquier longitud. Un carpintero puede clavar listones para 32 á 50 m cuad de enlucido en un día de 10 horas, según el número de ángulos que tenga el cuarto, etc.

# EMPIZARRADO

**Las pizarras para techos** son generalmente de 3 á 6 milímetros; término medio 4½ milímetros de espesor. Se pueden clavar sobre un forro de tablas ordinarias (*e*, *g*, en la figura) con un espesor de 2 á 3 cm (las que deben estar, y lo están rara vez, machihembreadas), colocadas horizontalmente de par á par ó inclinadas



de parecillo á parecillo, según sea el caso; ó en listones fuertes *ttt* como de 5 á 8 cm de ancho y de 2½ á 3 cm de grueso, clavados sobre los pares á distancia, de modo que se adapten á los bordes de las pizarras. Se emplean dos clavos para cada pizarra, uno cerca de cada esquina superior. Deben ser de cobre (que son más durables, pero más caros), de cinc, ó de hierro galvanizado ó estañado. Los dos últimos se emplean generalmente en trabajos inferiores. Los de hierro ordinario se hacen hervir previamente en aceite de linaza como un preservativo parcial contra la oxidación. El óxido, sin embargo, los debilita á veces tanto, que se rompen y las pizarras son arrastradas por el viento con peligro para los transeuntes. Como las pizarras buenas duran muchos años, es una verdadera economía el uso de clavos que sean igualmente durables. En armaduras de hierro, las pizarras en lugar de ser clavadas sobre tablas se atan á veces directamente á las piezas de hierro por medio de alambres. Un cuadrado (*square*) de empizarrado, de teja manila, etc., tiene 100 pies cuadrados (9.29 m cuad).

En los laboratorios, factorías químicas, etc., que están expuestos á emanaciones ácidas, es difícil encontrar, para amarrar, un metal que no se corroa. En tales casos es mejor colocar entre pizarra y pizarra una capa de mortero, la cual se endurecerá antes de que las ligaduras de metal cedan y mantendrá las pizarras en su lugar mientras se ponen ligaduras nuevas.

El menor declive que se le debe dar á un techo para impedir que la lluvia y la nieve se introduzcan por los intersticios de las pizarras, es como de 26 1/2°, ó sea 1 de altura para 2 de base, lo cual corresponde á una elevación de ½ de la luz en un techo común de dos aguas. Pero aun con mayores declives, la lluvia y la nieve sobre todo penetran á través del techo impulsadas por el viento fuerte, especialmente si se usan sólo listones y aun usando sólo entablado. Para evitar esto se puede poner una capa de mortero como de 6 mm de grueso sobre las superficies de contacto de las pizarras, si están sobre listones. Si sobre tablas, puede aplicarse el mismo procedimiento, ó el más común de cubrir primero las tablas con una capa de lo que se llama fieltro de empizarrar (*slating felt*), pero que en realidad es papel grueso obscuro remojado en alquitrán. Éste se vende en largos rollos de 71 cm de ancho, que pesan de 18 á 23 kg. Un rollo de 23 kg cubrirá como 28 metros cuadrados de techo. Tomando precauciones especiales contra la lluvia y la nieve, puede adoptarse una inclinación de 1 en 2½ ó hasta 1 en 3.

El espesor de pizarras en el techo es doble, excepto en los bordes *is*, *is*, etc., donde es triple. Los bordes que forman la junta se miden desde el hueco del clavo (debajo de *i*) de la pizarra de abajo, hasta el borde inferior ó *cabo s* de la superior, y es generalmente como de 7½ cm. A fin de que los bordes bajos visibles de las pizarras formen al colocarlos líneas rectas regulares á lo largo del techo, se hacen los huecos de los clavos á iguales distancias de la orilla inferior de las pizarras, de modo que cualquier irregularidad de tamaño quede escondida en la cabeza cubierta de la pizarra. El empizarrador calcula el tamaño de una pizarra desde el hueco del clavo en la parte superior hasta el borde inferior, despreciando la faja angosta comprendida entre el hueco del clavo y el extremo superior. Si de esta reducida longitud se deduce el borde de la junta, entonces la mitad de lo que queda será el *escantillón* ó margen de las hiladas de pizarra. El margen en m, multiplicado por el ancho de una pizarra en m da el área en m cuad de techo cubierto por una sola pizarra, y si se divide un m cuad por esta área, el cociente será el número de pizarras que se necesitan para un m cuad de techo. La parte superior de una pizarra se llama *dorso* y la parte inferior la *cama*.

El empizarrado, así como los techos de tejamaní, deben comenzarse del alero hacia arriba. Desde luego, las camas de las pizarras no son exactamente paralelas al entablado, y por consiguiente no descansan de plano sobre él; las situadas en el borde inferior del tejado ó en el alero *w* están espuestas á romperse fácilmente. Para impedir esto se clava primero cerca del alero una tira inclinada (un listón fuerte y ancho con su cara superior en bisel para que ajuste con la inclinación de las pizarras) á fin de que los extremos de la hilera más baja de pizarras descanse sobre ella. Esto se ve en una escala mayor en T.

Las pizarras de mejor calidad tienen una apariencia brillante semimetálica, algo semejante á la de la superficie de un papel frotado con lápiz negro. Las de aspecto opaco terroso son más blandas, más absorbentes y por consiguiente más susceptibles de ceder á las influencias atmosféricas, como las lluvias, heladas, etc. Se encuentran piritas de hierro frecuentemente en las pizarras, y como siempre se descomponen y dejan huecos, no deben admitirse nunca en los techos. Entre dos clases de pizarra, la mejor es generalmente la que, sumergidos dos pedazos de igual tamaño en un poco de agua durante una ó dos horas, absorba menor peso de dicho líquido, pues es menos susceptible de romperse por las heladas y descomponerse por la temperatura. Esta prueba se hace fácilmente.

En Inglaterra los diferentes tamaños se distinguen por nombres absurdos sin significación alguna. En los Estados Unidos se llaman pizarras de 6 por 12, de 16 por 24, etc., según sus dimensiones en pulgadas. Pueden cortarse, según se pidan, de cualquiera dimensión ó forma. Las de uso común varían de 18×36 á 30×46 cm. La primera forma hileras de 12½ á 15 cm y la última de 18 á 20 cm, según la distancia á que se han hecho los agujeros para los clavos de la cabeza. Mientras más distantes, más firme será el empizarrado.

Los techos de pizarra, así como los de hierro, calientan mucho las habitaciones que cubren. Esto disminuye algo cuando las pizarras reposan sobre tablas en lugar de estar sobre listones, y todavía más, cuando hay debajo una capa de yeso ó de encalado. También son susceptibles de quebrarse cuando se camina sobre ellas, pero esto sucede menos cuando están colocadas sobre mortero.

### Peso de los techos de pizarra.

El metro cuadrado de pizarra de .003 m de espesor pesa $1 \times .003 \times 2{,}800 = 8.4$ kg; el de .0047 de espesor pesa $1 \times .0047 \times 2{,}800 = 13.16$ kg; y de un espesor de .0063 pesa $.0063 \times 1 \times 2{,}800 = 17.64$ kg. Su densidad es 2.8. Pero debido á la superpo-

sición de los bordes, un metro cuadrado de techo requiere como 2½ m cuadrados de pizarra de tamaño ordinario, y si las pizarras están colocadas sobre tablas de 2½ cm de grueso, el peso por m cuadrado de techo aumentará como en 11 kg; si son tablas de 3 cm, como en 14 kg. Los listones pesarán como 1.22 kg por m cuadrado.

| Peso aproximado del empizarrado. | | | | | | Peso en kg por m cuad. |
|---|---|---|---|---|---|---|
| Pizarras de | ⅛ | pulg (3 mm) | de espesor | sobre | listones | 23.192 |
| — | — | — | — | — | tablas de 1 pulg (25 mm) | 32.958 |
| — | — | — | — | — | — de 1¼ pulg (32 mm) | 35.643 |
| — | 3/16 | — (5 mm) | — | — | listones | 34.178 |
| — | — | — | — | — | tablas de 1 pulg (25 mm) | 43.944 |
| — | — | — | — | — | — de 1¼ pulg (32 mm) | 46.629 |
| — | ¼ | — (6 mm) | — | — | listones | 45.164 |
| — | — | — | — | — | tablas de 1 pulg (25 mm) | 54.929 |
| — | — | — | — | — | — de 1¼ pulg (32 mm) | 57.61 |

Si se emplea el fieltro de empizarrar (*slating felt*), agréguese 1.22 kg por m cuad, y si se colocan las pizarras sobre 6 mm de mortero, agréguense 14.65 kg por m cuad.

Al peso total soportado por la armadura de un techo debe agregarse también el peso de los parecillos. Éste variará de 7.32 á 14.64 kilogramos por metro cuadrado en techos de luz moderada. Agréguese por el viento y la nieve unos 98 kg por m cuadrado y agréguese finalmente el peso de la misma armadura.

Para coger las juntas de las pizarras (ó tejamaní) y chimeneas, claraboyas, etc., es muy buena una mezcla fuerte de pintura de albayalde tal como se vende por cuñetes, y con arena suficiente para impedir que se esparza, especialmente si se protege por una cubierta de tiras de plomo ó cobre, hojalata, etc., clavadas á las juntas del mortero de la chimenea después de doblarlas, para que penetren en dichas juntas, las cuales deben escarbarse hasta 2½ cm de profundidad y rellenarse luego. A menudo se usa también con este objeto el mortero, protegido de la misma manera y aun sin proteger, pero no es tan bueno como la pintura y la arena. Se usa con igual fin el mortero de algunos días de preparado (para dejar que absorba algunas partículas refractarias de cal) mezclado con cenizas de herrería y melaza (*molasses*) y así se endurece mucho y es muy eficaz.

# TEJAMANÍ

Las tejamanís de cedro blanco son las que se usan con mejores resultados y cuando son de buena calidad duran de 40 á 50 años en nuestros Estados del Norte. Son generalmente de 69 cm de largo por 15 á 18 cm de ancho; como 6 mm de espesor en el extremo superior y como 15 mm en el extremo inferior ó punta. Se colocan en hileras como de 20 á 21 cm de ancho, de modo que sólo ⅓ de la tejamaní queda expuesta á la intemperie. Generalmente se colocan en capas triples, excepto en un espacio de 2½ á 5 cm en los extremos superiores donde entran cuatro. Se clavan sobre listones aserrados de roble ó de pino amarillo como de 4.88 m de largo, 6 cm de ancho y 2½ de grueso, colocados en hileras horizontales á distancias de 22 cm. Éstos se clavan en los pares los que, para listones de dimensiones anteriores, no deben estar separados más de 60 cm de centro á centro. Se emplean dos clavos para cada teja, los cuales se clavan cerca de su extremo superior. No deben ser más pequeños que de á 880 en kg. Los clavos forjados son los mejores por ser los más fuertes; los cortados se quiebran al cimbrarse la tejamaní. Son suficientes, para cien m cuadrados, unos 10 kg de clavos, incluyendo desperdicios. Una tejamaní mediana de 19 cm de ancho en hileras de 21½ cm deja ver cuatro decímetros cuadrados y requiere como 25 tejas por m cuadrado. Pero, tomando en cuenta los desperdicios y las tejas angostas, es conveniente calcular en la práctica unas 10 tejas más por m cuadrado. Tanto techando con tejamaní como empizarrando, es natural empezar

de los aleros hacia arriba. Para coger las juntas entre las tejas y las chimeneas, claraboyas, etc., véase el final del artículo Empizarrado.

El ciprés y el pino blanco son también muy usados para tejamaní, pues son mucho más baratos; pero apenas duran la mitad de aquéllos. Todas las tejamanís se adelgazan con el tiempo por la lluvia y la intemperie. En los climas cálidos y húmedos se pudren de los 6 á los 12 años.

# PINTURA

El principal material usado en la pintura de los edificios es el blanco de plomo (albayade) ó el óxido de cinc mezclado con aceite de linaza crudo sin hervir, con la consistencia de una pasta gruesa. Así lo venden en cuñetes los fabricantes. Para prepararlo cuando se va á usar, sólo se necesita agregarle más aceite de linaza: como .38 á .50 litros por kg de la pintura en cuñete para adelgazarlo lo suficiente á fin de que corra fácilmente la brocha.

Una pintura buena necesita de 4 á 5 manos; pero sólo se usan generalmente 4 para las habitaciones principales y 3 para las inferiores. Cada mano debe dejarse secar perfectamente antes de que se dé la otra.

Un kilogramo de pintura del cuñete, adelgazada como queda dicho, da 3.70 m cuad de primera mano; 5.50 de segunda mano y 7.40 de cada una de las subsiguientes, ó lo que es lo mismo, 1 m cuad con tres manos requiere 580 gramos de pintura: 1 m cuad de 4 manos, 720 gramos, y uno de 5 manos, 860 gramos. La primera mano necesita más que las subsiguientes porque la superficie desnuda de la madera absorbe más pintura.

Cuando, como es costumbre, se usa aceite *crudo* de linaza para adelgazar, se le deben agregar *secantes*, porque de otro modo la pintura necesita varias semanas para endurecerse, mientras que con secantes sólo de 2 á 3 días (según la temperatura) serán suficientes para que cada mano se endurezca y pueda recibir la otra. Los secantes que se usan más generalmente son litargirio pulverizado en la proporción de una cucharadita de te colmada; ó barniz japonés, 1 cucharada de las de sopa para 4½ kg de la pintura. Azúcar de plomo (sal de saturno) ó sulfato de cinc, pueden usarse también en lugar de litargirio, y en la misma proporción. Aun cuando el litargirio y el barniz japonés son obscuros, la cantidad es tan pequeña que no afecta apreciablemente la blancura de la pintura. Si se usa el barniz con exceso, como á menudo se hace para terminar el trabajo de prisa, produce agrietamientos en toda la superficie. No es necesario ningún secante si se usa aceite crudo para adelgazar. No basta solamente hervir el aceite; para que se endurezca más rápidamente, los pintores le echan previamente litargirio antes de hervirlo, en la proporción de 15 gramos por litro. En algunas obras escritas para el uso de los pintores de edificios, se asegura que el aceite se pone demasiado espeso para cualquier trabajo que no sea exterior, cuando se hierve. Pero esto es un error; porque si se hierve bien el aceite, quedará suficientemente delgado para el más fino trabajo interior, y será además más transparente que cuando está crudo, dando á la superficie que se pinta una apariencia más brillante. El calor debe ser tan sólo el necesario para que hierva, es decir, como 355° C. El hervor debe continuar como 1½ horas, removiendo el aceite de cuando en cuando para que el litargirio no se asiente. Se puede dejar entonces apaciguar el fuego y la operación estará terminada. Se habrá formado un sedimento en el fondo, el cual se dejará al trasegar el aceite. Aun cuando con este aceite no se necesita emplear ningún secante, se le puede agregar, sin embargo, un poquito de litargirio cuando se requiera gran prontitud. Los pintores usan rara vez este aceite, debido á que les resulta un poco más costoso.

Otra substancia muy usada para adelgazar el aceite (excepto en la primera mano) es el espíritu de trementina. La cantidad de aceite puede disminuirse en proporción á la trementina que se agrega. Siendo ésta más fluida que el aceite, hace que la pintura corra mejor con la brocha. Disminuye además la tendencia que tiene á ponerse amarilla, especialmente en los cuartos que se conservan cerrados por algún tiempo. Es además más barata que el aceite. No debe emplearse para trabajos exteriores expuestos á la intemperie, ó debe limitársela moderadamente, puesto que tiende á endurecer la pintura, y aun cuando sus efectos se pueden apreciar

apenas en el interior, son verdaderamente visibles cuando el trabajo tiene que estar á la intemperie. Según el gusto, en la pintura de los edificios á veces se desea que la superficie sea de una apariencia brillante y otras veces está en boga un color apagado ó mate. La apariencia brillante es la que tendrá naturalmente la pintura siempre que no se use al adelgazarla más trementina que aceite. El color mate se obtendrá no usando aceite, sino trementina sola, para la última mano, que se llama mano *apagada*. Aun cuando la trementina no es propiamente un secante, como se evapora pronto, ayuda á aclarar la pintura.

Para trabajos exteriores se recomienda generalmente el uso de más secante que para los interiores á fin de que la pintura pueda endurecerse ó secar bastante pronto y para que el polvo y la lluvia no la dañen. En otros casos es mejor emplear menos.

Cuando en vez de una mano final se quiere dar otro color, la substancia colorante se mezcla con la pintura blanca que va á usarse en la última mano solamente; hay veces que son necesarias dos manos de pintura de color, antes de producir un efecto satisfactorio. Las materias colorantes pueden ser añil, negro humo, tierra de siena, tierra de sombra, ocre amarillo, cromo, rojo de venecia, minio, etc., etc., las cuales van mezcladas con aceite y preparadas para la venta por los fabricantes de pinturas de albayalde y cinc. Aquellas están simplemente bien unidas con pintura blanca.

Toda superficie que se va á pintar debe primero secarse perfectamente y quitársele el polvo. Si es sobre madera, debe quitársele á ésta las marcas del cepillo y otras pequeñas irregularidades con papel de lija cuando se desea un pulimento más fino. También se deben hacer penetrar las cabezas de los clavos como 3 mm debajo de la superficie. Para impedir que los nudos se vean á través del pulimento (como sucedería con el pino blanco y amarillo debido á la trementina que contienen), se deben tapar por medio de dos manos de goma laca, que al secarse se pule con lija fina. Otro modo, no tan seguro, consiste en una ó dos capas de albayalde mezclado con agua de cola delgada ó « encolado », como se dice.

Después de estos preparativos, se pone la primera capa, ó capa de aparejo, en la cual no debe haber trementina; porque penetraría de pronto en la madera, dejando sólo el albayalde en estado casi seco y quebradizo. Hecho esto, los huecos de los clavos, rendijas, etc., deben rellenarse con mastique hecho de blanco de España (fino y lavado) y aceite de linaza crudo; el aceite cocido no da buen resultado; la pasta saldría friable. Dicha pasta estaría expuesta á caerse si se pusiera antes de la capa de aparejo; porque la madera absorbería el aceite y se contraería aquélla. Después de que la primera capa esté perfectamente seca, se pondrá la segunda, y para ella, se mezclará uno de trementina con tres del aceite de adelgazar. En la tercera y cualesquiera de las capas subsiguientes se pueden usar iguales partes de trementina y aceite, para adelgazar, si se quiere que la pintura al secar quede con *lustre;* pero si se desea de color mate, la última capa debe ser apagada ó enteramente sin aceite, sustituyendo éste por la trementina.

Los pintores limpian sus brochas, generalmente, quitándoles casi toda la pintura con un cuchillo, y conservándolas en agua hasta que las vuelvan á usar. Si se tienen que guardar por algún tiempo, deben limpiarse muy bien con trementina ó con jabón y agua. Para impedir que se forme una costra dura sobre la pintura; cuando se deja de usar la brocha por algunos días, se le pone un poco de aceite.

**Las mejores pinturas para preservar el hierro expuesto á la intemperie** parecen ser los óxidos de hierro pulverizados, tales como el ocre de hierro amarillo y el rojo, ó hematita obscura de hierro mineral, bien pulverizada y mezclada simplemente con aceite de linaza y un secante. El albayalde aplicado directamente al hierro hace necesario renovarlo constantemente y es probable que ejerza una acción corrosiva. Puede aplicarse, sin embargo, sobre colores más durables cuando las apariencias lo exijan. Se dice que el almagre es muy durable cuando está puro. Se nos presentan como un ejemplo, las varillas de una bomba en un aljibe de 61 m de profundidad que está cerca de Londres, que habiendo sido pintadas así primero, estuvieron en uso por espacio de 45 años, á cuyo término se encontró que su peso era exactamente el mismo que cuando nuevas, demostrando con esto que el moho no las había afectado.

Cuando las dimensiones de la superficie del hierro expuesto lo permitan, puede prevenirse en gran manera, contra el moho, calentándole muy bien primero y luego lavándole bien con aceite de linaza caliente, el cual penetrará entonces en el interior del hierro. Para el hierro estañado expuesto á la intemperie, en techos, canales, etc., el ocre obscuro es un color muy durable. El estaño se encuentra á menudo en per-

fecto estado de conservación y pulimento, después de 40 y 50 años de uso. La pintura blanca se cae con la lluvia en pocos años.

Las paredes encaladas ó enlucidas deben dejarse secar por lo menos un año, si es posible, antes de pintarlas al óleo, porque de lo contrario la pintura está expuesta á ampollarse. Si se quiere, durante este intervalo puede pintarse al fresco.

La pintura sobre maderas verdes ó no bien secas, contribuye á que se piquen. Si la superficie que se quiere pintar es grasosa, la grasa debe quitarse primero con agua en la cual se disuelve un poco de cal.

**Pinturas al temple para trabajos exteriores.** Downing, en su obra sobre casas de campo, recomienda lo siguiente. (*Obs. del T.* — Hemos hecho las conversiones.) Para construcciones de madera: Tómense 20 litros de cal viva y apáguense en un envase de capacidad doble hechándole agua hirviendo hasta cubrirla con una capa de líquido de 10 á 12 cm, se mueve bien hasta apagarla y se le agrega 1 kilogramo de sulfato de cinc, luego se agrega agua como se dijo hasta que tenga la consistencia de una lechada gruesa y se aplica con una brocha de dar lechada. Esta lechada es blanca, pero puede colorarse agregándole ocre en polvo, almagre, tierra de sombra, etc. Si se agrega negro humo á las acuarelas (pinturas líquidas), debe primero disolverse perfectamente en alcohol. El sulfato de cinc hace que la lechada se endurezca en pocas semanas.

**Para ladrillo, mampostería ó fundición en bruto.** Apáguense 20 litros de cal como se dijo anteriormente, llénese entonces ¾ partes del depósito con agua y agréguese otro volumen igual de cemento hidráulico, agréguense 1 ½ kilogramos de sulfato de cinc previamente disuelto en agua. Todo debe tener la consistencia de la pintura y se puede poner con una brocha de dar lechada. Esta pintura se mejora mezclándole 10 lit de arena blanca antes de usarla. Se le puede dar color como se hizo antes.

El mismo autor da también la siguiente pintura al óleo, barata, para madera, ladrillo y piedra, á la intemperie: Una medida de cal viva fresca molida, agréguese la misma cantidad de arena fina, ó ceniza fina de carbón mineral, y el doble de ceniza fresca de leña; todos estos ingredientes se pasan por un cedazo fino. Mézclese todo en seco. Póngasele suficiente aceite crudo de linaza para que la mezcla sea tan delgada como la pintura. Aplíquese con una brocha de pintor. Se le puede dar color como las anteriores, teniendo cuidado de mezclar bien los colores antes de agregárselos. Sería conveniente dar dos manos; la primera delgada y la segunda espesa.

Otra pintura que se dice, dura de 15 á 20 años, es la siguiente: 23 kg de albayalde de superior calidad, 9.45 litros de aceite de linaza crudo, 230 gramos de secante, 23 kg de arena aguda cernida fina, 900 gr de tierra de sombra cruda. Agréguesele un poco de trementina; como ½ litro. Aplíquese con una brocha *ancha*.

**Cemento para coger las juntas** alrededor de las chimeneas, etc., etc. Albayalde en aceite, como se vende en cuñetes, mezclado con arena suficiente para formar una pasta dura que no corra. Se endurece al aire y resiste el calor, el frío y el agua. Se pueden pegar fuertemente pedazos de piedra con este cemento dejándolo secar bien durante algunos meses para que se endurezca.

**Lechada para trabajos al interior.** Según Mr. Downing, se hace más firme y permanente agregándole 2 lit de *aparejo* delgado á una lata de lechada, poco antes de usarla. El mejor aparejo para este objeto es el agua de cola. Debemos añadir que no se debe permitir, como comúnmente se hace, ponerle sal á la lechada. El papel pegado á un muro al que se le ha dado lechada salada, se humedece, se despega y se cae en tiempo de humedad. Se debe raspar la lechada, y luego cubrir las paredes con una ó dos manos de agua de cola para proteger el papel del efecto de la sal que se haya quedado adherida al encalado.

# VIDRIOS Y VIDRIERAS

Los vidrios para ventanas se venden por cajas. Cualquiera que sea el tamaño de las láminas, una caja contiene tan cerca de 50 pies cuadrados=4.64 m cuad de vidrio como lo permitan las dimensiones de aquéllas.

Se fabrican en láminas de cualquier tamaño según se pidan. El vidrio ordinario tiene más ó menos 1.6 mm de grueso, y se sobrentiende que tiene ese grueso mientras no se especifique mayor. El vidrio de *doble espesor* tiene casi 3.2 mm y su precio es 50% más que el de *espesor sencillo*. Por supuesto que es mucho más fuerte que aquél

Las láminas se fijan en los marcos con pasta hecha de blanco de España y aceite de linaza, y con pequeños pedazos de hojalata triangulares como de 6 mm por lado, que mantienen fijo el vidrio mientras se le pone la pasta y se le dejan para que le sirvan de mayor protección mientras la pasta está blanda.

Las mejores clases de vidrios americanos se hacen en las cercanías de Filadelfia, Boston y Pittsburg, etc., y son tan buenos para uso común como los fabricados en el extranjero; pero cuando se desea un alto grado de *belleza*, como en las ventanas de los pisos bajos de las casas lujosas, los escaparates de las tiendas, etc., se deben emplear los vidrios pulidos fabricados en Inglaterra, Francia y Alemania, aunque los precios por láminas de tamaño moderado son de 5 á 8 veces mayores que los mejores de espesor sencillo hechos en los Estados Unidos. Su superficie, perfectamente *lisa*, libre de reflejos deformadores, también los recomiendan como los mejores para cubrir dibujos, pinturas, etc.; sin embargo, si se emplean vidrios americanos cuidadosamente escogidos para este último objeto, pocos conocedores podrían distinguir la diferencia.

**Se fabrica un vidrio grueso especialmente para pisos**, hasta de 2½ cm de grueso y hasta de 1.27×2.75 m de superficie; también se hace para claraboyas de 6 á 12 mm de espesor. Este último se hace á la orden de cualquier tamaño hasta de 1 m×2.4 ó 3 m. Los tamaños pequeños se pueden conseguir *esmerilados*. La opacidad (esmerilado) impide la entrada de toda la luz del sol, y sin embargo difunde la luz en mucho mayor espacio.

**Resistencia del vidrio.** Tensión de 175 á 630 kg por cm cuad. Barras de Boston, probadas por el autor, 245 á 364. Resistencia á la trituración 420 á 700 kg por cm cuad. Transversalmente (según los ensayos del autor), vidrio de piso de 2½ ×2½ cm y 30 cm de luz, entre los apoyos, se rompe con una carga central de unos 77 kg; por consiguiente, es considerablemente más fuerte que el granito, excepto en lo que respecta á la trituración, en la cual los dos son casi iguales.

*Observación.* El vidrio para ventanas y otros, que contienen un exceso de potasa ó de soda, están expuestos á hacerse opacos con el tiempo, debido á la descomposición de aquellos ingredientes por las influencias atmosféricas.

## CUERDAS Y CABLES

**La resistencia** de las cuerdas varía mucho. Pedazos del mismo rollo pueden variar en 25%. La siguiente tabla se basa en un promedio de calidad **Manila**. El buen **cáñamo italiano** es considerablemente más fuerte. Se dice que el **alquitranado** en los cordeles disminuye su resistencia, y que cuando están á la intemperie, también les reduce su durabilidad. Creemos que su uso en aparejos verticales tiene por resultado disminuir su contracción y su expansión por el cambio de humedad y sequedad en la atmósfera. Algunos meses de **trabajo á la intemperie** debilita los cables de 20 á 50 por ciento.

(*N. del T.* — Hemos convertido la tabla del autor al sistema métrico.)

**Tabla de cuerdas de Manila.**

| Diám. | Circunf. | Peso por m. | Carga de ruptura. | Diám. | Circunf. | Peso por m. | Carga de ruptura. |
|---|---|---|---|---|---|---|---|
| mm. | mm. | kg. | kg. | mm. | mm. | kg. | kg. |
| 6.0 | 19.0 | .03 | 254 | 48.5 | 152.4 | 1.77 | 11580 |
| 8.1 | 25.4 | .05 | 355 | 52.6 | 165.1 | 2.07 | 13206 |
| 12.1 | 38.1 | .11 | 711 | 56.6 | 177.8 | 2.41 | 14831 |
| 16.1 | 50.8 | .20 | 1239 | 60.7 | 190.5 | 2.77 | 16457 |
| 20.2 | 63.5 | .31 | 1940 | 64.8 | 203.2 | 3.14 | 18082 |
| 24.3 | 76.2 | .44 | 2773 | 72.6 | 228.6 | 3.98 | 21333 |
| 28.2 | 88.9 | .60 | 3870 | 80.8 | 254.0 | 4.92 | 24583 |
| 32.3 | 101.6 | .79 | 5243 | 88.9 | 279.4 | 5.94 | 27839 |
| 36.3 | 114.3 | 1.00 | 6706 | 97.0 | 304.8 | 7.08 | 31091 |
| 39.4 | 127.0 | 1.23 | 8330 | 105.1 | 330.2 | 8.31 | 34342 |
| 44.4 | 139.7 | 1.49 | 9957 | 113.0 | 355.6 | 9.63 | 37590 |

**Cargas de trabajo.** Para cables de Manila, de 25 á 45 mm de diámetro, corriendo á varias velocidades sobre poleas de diámetros fijos, Mr. C. IV. Hunt (Trans. Am. Soc. Mechl. Engrs., vol. XXIII, 1901) da una tabla conteniendo aproximadamente los siguientes resultados de su experiencia. Carga de trabajo = C × resistencia máxima de un cable nuevo. D = diámetro mínimo de polea, en mm. (Convertidas por el T.)

| Velocidad. | m por min. | en trabajo de | C | Cable de 25 mm. D | Cable de 45 mm. D |
|---|---|---|---|---|---|
| Despacio... | 15 á 30 | grúa, martinete, etc., muelle. | .140 | 200 | 350 |
| Mediano... | 45 á 90 | de cantera, carga..... | .056 | 300 | 450 |
| Rápido.... | 120 á 240 | | .028 | 1000 | 1780 |

Estos cables se destruyen rápidamente. Un cable de 37 mm de diám se destruye cargando de 7,000 á 10,000 toneladas de carbón. Por otra parte, cables de transmisión de 37 mm, corriendo á la velocidad de 1,500 m por minuto y llevando 1,000 caballos de vapor por poleas de 1.50 y 5 m de diámetro, duran años.

Las cifras de Mr. Hunt para la resistencia máxima, basadas en pruebas hechas con cuerdas de Manila, de tres diferentes fabricantes y compradas en el mercado público, son prácticamente idénticas á las que damos en nuestra tabla anterior, así como las del prof. B. Kirsch, del Musco Imperial y Real de Tecnología Industrial, de Viena, citadas por Mr. Hunt.

## PESOS Y RESISTENCIAS DE LOS CABLES DE ALAMBRES

Cables fabricados por **John A. Roebling Sons Co., de Trenton, N. J.,** y otros. Los precios y los pesos dados se refieren á cables con el eje de cáñamo Cuando se fabrican con ejes de alambre los pesos aumentan en un 10%. El cable «**Hércules**» de **A. Leschen and Sons Rope Co., de San Luis, Mo.,** tiene una resistencia y precio 50% mayor que el cable de acero colado.

(*N. del T.* — Las tablas del autor convertidas al sistema métrico.)

| 25 | 7.14 | .18 | 1.4 | 2.8 | .68 | .45 | 10 | 13 |

**Notas sobre el empleo del cable de alambres,** por la Compañía Roebling.

Los cables con 19 alambres por torcido son los más flexibles y por consiguiente los más apropiados para **suspender** y **deslizarse.** Los otros son más rígidos y más apropiados para **vientos** ó **tirantes,** etc. Los cables de hierro y acero,

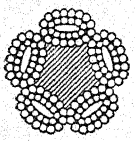
* **Para carga de trabajo y de seguridad,** tómese un quinto ó un séptimo de la de ruptura de acuerdo con la velocidad.

hasta de 76 mm de diámetro, se hacen á la orden. Los cables de ejes de henequén son más flexibles que los de eje de acero. Los cables de alambres no se deben **arrollar** ó **desarrollar** como los de cañamo. Cuando están en un carrete, éstos deben montarse en un eje ó en una mesa giratoria para ir desarrollando el cable. Cuando se envía en un bulto, sin carrete, arróllese el cable en el suelo como una rueda, y asi mismo se debe desarrollar. Evítese destejerlo y hacer dobleces pequeños. **Para conservar los cables de alambre**, pónganseles aceite de linaza crudo (que se puede mezclar con una cantidad igual de negro humo ó pintura obscura) con un pedazo de cuero de carnero, con los pelos hacia el cable. **Si se va á usar bajo el agua ó subterráneo**, agréguesele 36 lit de cal acabada de apagar ó un poco de aserrín para 1 barril de alquitrán. Hiérvase bien la mezcla y satúrese con ella el cable, mientras aquélla está caliente.

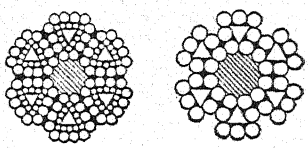
Los cables de **alambre galvanizado** para aparejos son más durables y más baratos que los de cáñamo, y no se estiran constantemente con los grandes esfuerzos. Su volumen es $^1/_6$ y su peso ½ del de cáñamo. Los cables de acero colado en crisol son mucho más durables que los de hierro. Deben mantenerse bien lubricados.

## Cable patentado de acero achatado y estirado.

**Fabricado por A. Leschen and Sons Rope Co., de San Luis, Mo**



Cables de suspensión.



Cables de tracción y de transmisión.

El papel de dibujo inglés es más fuerte y mejor que el americano. El de Whatman tiene una gran reputación; lo hay, sin embargo, de diferentes calidades. Cuando el papel está pegado en muselina, la diferencia en la calidad no es tan importante. Para el papel en rollos, las fábricas alemanas son las mejores. Se importa poco de otras fábricas.

**Tanto el papel blanco como el de color**, para el uso de los ingenieros, se hace en rollos continuos sin empates. Ancho, 91.4, 106.7, 137.2, 147.3 y 157.5 cm; longitud ordinaria, 36.57 m; pero se pueden obtener, encargándolos, hasta de 365.75 m de largo ó más. Éste puede comprarse ya pegado en muselina, en rollos de 9 á 36 m de largo.

El papel de **cartuchos** ó el papel **de modelos** se venden en rollos largos de la misma longitud que el papel blanco, montado ó no en tela; ancho, hasta 1.37 m. Color de ante claro.

**Papel de calcar.** La mayor parte del que se vende, ya sea del país (E. U.) ó del extranjero, es tan fácil de romper, que relativamente es de poca utilidad.

El papel de pergamino, de 94 y 96½ cm de ancho, en rollos de 18.28 y 21 m, es mejor, pero no coge la tinta perfectamente.

**La tela de calcar** es muy preferible al papel de calcar, por su gran resistencia. Ancho, 45.7, 76.2, 91.4 y 106.7 cm; longitud hasta 22 m.

**El papel para perfiles** se hace en anchos de 22.9 y 50.8 cm y en pliegos sencillos ó en rollos largos continuos.

**Papel para secciones** transversales montado ó sin montar, así como el de calcar y la tela, se venden en pliegos ó en rollos, cuadriculados en quintos, octavos, décimos y duodécimos de pulgada, ó en milímetros.

**Colores.** Desde que se introdujo el uso de las impresiones azules, se hacen pocos dibujos en colores, excepto para efectos arquitectónicos; pero los colores se usan con ventaja en las impresiones de líneas negras calcadas, pág. 1076. Un buen dibujante necesita pocos colores, como rojo de almagre, azul de Prusia, laca ó carmín rojo claro, tierra sombra quemada, tierra siena quemada, tierra siena cruda, gutagamba, ocre romano y verde vegetal. No se debe comprar sino la mejor tinta de China. Las pastillas de colores deben siempre secarse en papel, después de haberlas lavado con agua, y para esta operación se debe emplear poca agua, y luego aumentarla.

**Lápices.** Los *legítimos* de A. W. Faber, n.º 2, 3 y 4, son muy buenos. Su dureza aumenta con el número. Los n.º 3 y 4 sirven para la cartera de mensuras, dependiendo la preferencia de la clase del papel. Sus lápices marcados con letras son de la mejor calidad y mejores para el dibujo. « H » significa « duro » (« *hard* »), « B », « blando » (« *soft* »). Los grados de dureza ó blandura se indica por el número de « H » y de « B ». « F » (intermedio) corresponde al n.º 3. Los lápices americanos de Dixon son buenos. El dibujante en su oficina debe tener una lima plana, ó un pedazo de papel de esmeril pegado en una tira de madera, en la cual afile con facilidad la punta del lápiz, después de usar la cuchilla.

* *N. del T.* — Los números entre paréntesis son las dimensiones en centímetros.

# IMPRESIONES EN AZUL, ETC.

**Art. 1.** (a) Para obtener los mejores resultados, se debe evitar toda **exposición innecesaria** ya sea del papel sensibilizado ó de la solución, á la luz del sol ú otra luz blanca.

(b) La **limpieza** es de la mayor importancia. Los envases en que se hacen y se mezclan las soluciones deben estar escrupulosamente limpios, y, si se lavan con jabón, se deben enjuagar muy cuidadosamente con agua limpia. Deben mantenerse llenos de agua cuando no estén en uso. La presencia de álcali libre de cualquier clase, es fatal para el buen resultado, y destruye inmediatamente el color azul de la impresión. Véase art. 19 (b). No se debe permitir que las soluciones se pongan en contacto con hierro.

**Art. 2.** (a) **La solución** que se emplea para sensibilizar el papel para impresiones en azul es generalmente la de *ferro*cianuro de potasio (ó sea prusiato rojo de potasa) * y amoniocitrato de hierro (citrato de hierro y amoníaco) en agua.

(b) Generalmente se **disuelven las sales por separado** y se mezclan luego las dos soluciones. La sal de potasio se debe quebrantar en partes muy pequeñas. La sal de hierro es generalmente pura y se disuelve muy pronto. Se puede conservar indefinidamente en su estado sólido si está perfectamente seca, pero absorbe muy fácilmente la humedad y se hace pegajosa é inútil; la solución se puede espesar á los pocos días, ya esté sola ó mezclada con la solución de potasio. Por esto se debe preparar (en un cuarto obscuro) en pequeñas cantidades según se necesite.

**Art. 3.** (a) El siguiente es un promedio de varias **recetas** que han dado excelentes resultados:

Solución A. 1 onza de prusiato rojo de potasa para 6 onzas de agua, ó 2½ onzas de sal para una pinta (0.47 lit) de agua.

Disuélvase muy bien y filtrese. La solución se puede filtrar suficientemente en algodón crudo y mucho más pronto que en papel.

Solución B. 1½ onzas de amoniocitrato de hierro para 6 onzas de agua, ó 4 onzas de sal para ½ litro de agua.

Disuélvase muy bien. Filtrese, á menos que la solución esté perfectamente clara.

(b) Manténganse las dos soluciones en frascos distintos provistos de tapas de vidrio, en un lugar obscuro hasta que se vayan á usar. Luego mézclense en partes iguales y filtrese la mezcla. Cuídese de que ninguna partícula sólida del prusiato rojo pase á la solución doble. Debe rechazarse cuando su color marrón se cambie en verde azulado.

(c) La solución combinada **cuesta** á los *amateurs* de 1 á 2 centavos por onza. Unas 4 onzas **bastarán** para cubrir 9 m cuad de papel.

(d) Si se agregan unas pocas gotas de una solución fuerte de amoníaco á la de citrato, B, hasta que el olor se haga perceptible, la adición de una solución saturada de **ácido oxálico** en agua á la doble solución, **precipita la impresión en tiempo nublado.** 10% de la solución de ácido oxálico aumenta la rapidez de la impresión como 2½ veces; 20%, 5 veces; 30 %, 10 veces; pero con más de 20 % es difícil obtener líneas blancas claras. En tiempo de sol la diferencia es mucho menos marcada. (*Engineering News*, dic. 15, 1892.)

**Art. 4.** (a) Cuando no se requiere un trabajo muy fino, cualquier **papel** bien preparado y suficientemente duro para soportar el lavado servirá. Para trabajos de importancia empléese papel de contextura uniforme, fina, lisa y de superficie dura, libre de substancias químicas dañosas. Si la solución penetra debajo de la superficie, una parte de los agentes químicos se queda en el papel, á pesar del lavado, y dañaría el resultado. Se hacen muchas clases de papeles para este objeto. El de Sajonia (alemán) y el de Rives (francés) se consideran como de los mejores. El papel de Johannot y Steinbach da buenas impresiones, pero no es muy fuerte. Los papeles de lino de Weston y de Escocia son más fuertes y dan excelentes impresiones. Antes de sensibilizar una gran cantidad de papel de una nueva clase, pruébese una pequeña hoja. La tela de lino para sensibilizar también se vende en las tiendas de materiales para fotografía y en las de materiales de ingeniería.

---

* *No* el *ferrocianuro* ó prusiato *amarillo*.

**Art. 5.** (a) La solución se aplica (en el cuarto obscuro, por supuesto) á un solo lado del papel. Esto se hace á veces haciendo *flotar* el papel sobre la solución, teniendo cuidado de que ésta no toque el *respaldo* del papel. Se sostiene el papel por dos esquinas opuestas diagonalmente y la línea que se forma se deja descansar en la superficie del líquido, luego se dejan caer las esquinas una después de otra. Se levanta una mitad á la vez para ver si se ha formado alguna burbuja de aire debajo de él. Si es así, se saca arrastrando sobre la solución aquella mitad del papel en la cual esté la burbuja, mientras se mantiene la otra mitad suspendida sobre el líquido. La operación de *flotar* se hace en uno ó dos minutos y luego se saca el papel haciéndolo resbalar sobre una de las orillas del depósito, y escurriendo el exceso de líquido. Este procedimiento requiere una cubeta mayor que el papel y el interior de ella debe no sólo ser impermeable, sino también á prueba de la acción química de la solución. Esta manipulación requiere un gran cuidado.

**Art. 6.** (a) La solución se aplica generalmente por medio de una *brocha* suave y ancha (semejante á la que se usa con los libros de copiar cartas) ó una *esponja* grande y suave libre de arena ú otros granitos de suciedad.

**Art. 7.** (a) Al aplicar la solución, puede colocarse el papel sobre una tabla cubierta de un *hule* suave, el cual se debe secar muy bien después de sensibilizar cada hoja, para evitar que se manche la otra.

(b) **La operación** debe hacerse rápidamente, de manera que ninguna parte de la hoja se seque antes que toda la superficie haya sido cubierta con la solución. Por esta razón, si las hojas son muy grandes las deben manejar dos personas. Cúbrase la hoja primero con pases de la esponja ó brocha mojada, muévase á lo largo del papel, é inmediatamente, con pases en ángulos rectos y con la esponja ó la brocha exprimida, de manera que la solución quede uniforme y finamente distribuída sobre toda la superficie. Lávese la esponja inmediatamente en el cuarto obscuro.

**Art. 8.** (a) Se cuelga el papel para que se **seque** en el cuarto obscuro, sujeto por agarradoras de resorte, ú otro medio, que no tengan partes de hierro. Las hojas pequeñas se pueden colgar por una punta; las grandes, por dos ángulos adyacentes ó por dos ó tres puntos más de la misma orilla, según su tamaño, teniendo cuidado de doblar ligeramente aquella orilla, de manera que el papel no se estire al secarse. Si se cuelgan las hojas en una barra, la solución se secará en el doblez con desigualdad. A fin de que los blancos de la impresión salgan claros, el aire debe estar caliente, para que el papel pueda secarse prontamente é impedir así que la solución penetre mucho.

**Art. 9.** (a) Téngase mucho cuidado de que el papel esté perfectamente seco antes de usarlo ó guardarlo y que se conserve *seco* y *en la obscuridad* hasta que se quiera usar. Si se prepara y resguarda cuidadosamente, conservará su sensibilidad por mucho tiempo, pero los mejores resultados se obtienen con papel fresco; no es conveniente conservarlo por más de un mes ó dos.

**Art. 10.** (a) **El papel de calcar**, ó la tela de calcar, debe ser de un tinte azulado y delgado (el papel amarillo retarda la impresión; véase el art. 15), debe ser tan transparente como fuese posible. Debe preservarse, antes y después del dibujo, de una larga exposición á la luz, la cual tiende á hacerlo opaco.

(b) Tanto antes como después de dibujado se debe mantener en plano ó arrollado, y no doblado, pues los dobleces hacen difícil que el dibujo se ponga en perfecto contacto con el papel sensibilizado al hacerse la impresión.

**Art. 11.** (a) **El dibujo** ó trazado debe hacerse con la mejor tinta de China, muy negra. Agregándole un poco de gutagamba ó amarillo cromo aumenta su opacidad. Las líneas trazadas con amarillo cromo y gutagamba se imprimen muy bien; pero el azul de Prusia ó el carmín deben hacerse más opacos agregándoles un poco de blanco de China ú otro blanco opaco. Pónganse los dibujos ante una luz fuerte, para descubrir en ellos las partes débiles de las líneas.

**Art. 12.** (a) **La impresión** consiste en exponer el papel sensibilizado á la acción de la luz, colocando el dibujo entre la luz y la superficie sensibilizada. **La luz eléctrica de arco** imprime más despacio que la luz solar directa, pero tiene la ventaja de su constancia en todo tiempo y á todas horas y de la fijeza de su posición. (Véase art. 16 a).

(b) Colóquese el marco con la cara perpendicular á los rayos de la luz, lo más que se pueda, y téngase cuidado de que no caigan sobre el dibujo sombras de árboles, edificios, etc.

(c) El papel debe manejarse en una luz débil para recortarlo ó ponerlo en el marco.

**Art. 13.** (a) Para obtener un contacto exacto entre el dibujo y el papel sensibilizado, se colocan generalmente en un *chassis* ó marco de impresión. (Véase art. 15.) Las partes esenciales de un marco común son : el marco mismo, una lámina de

vidrio transparente para el paso de la luz y un respaldo acolchonado, que por medio de agarradoras y resortes, comprimen las dos hojas de papel muy unidas, contra el vidrio.

(b) Se coloca el trazado en el marco con el lado del dibujo hacia el vidrio y luego el papel sensibilizado en contacto con el dibujo por su cara sensibilizada. (Pero véase art. 16 b.) Por último, se coloca el respaldo acolchonado en el marco.

(c) Generalmente se hace el respaldo en dos piezas unidas por una visagra y cada una provista de un resorte, de manera que una mitad se pueda levantar para examinar el progreso de la impresión, mientras que la otra mitad permanece fija por la agarradora y mantiene fijos el papel sensibilizado y el trazado.

(d) Empleando un marco abierto en ambos extremos se pueden usar largas tiras de papel sensibilizado, por partes, arrollando el resto en los extremos del marco y envolviéndolo para protegerlo de la luz.

(e) Es muy importante que todos los marcos tengan vidrios suficientemente gruesos para soportar la presión necesaria á fin de obtener el contacto exacto de los dos papeles; deben ser de excelente calidad y sin defectos que puedan obstruir ó refractar imperfectamente la luz. (Véase art. 15., más abajo). Debe limpiarse muy bien el vidrio antes de imprimir.

(f) Los marcos de impresión mejorados tienen cojinetes de caucho y aire comprimido en lugar de acolchonado de lana al respaldo. En otros se hace la presión necesaria por medio del vacío producido entre el trazado y el vidrio por una bomba.

(g) Los marcos de impresión se compran en los almacenes del ramo. Sus precios, incluso el vidrio, varían de $2 por marcos de 25×30 cm á $30 ó $45 por los de 90×150 cm. Se pueden también obtener marcos montados en rodillos, con accesorios para exponerlos fuera de las ventanas, á precios que varían con las dimensiones y requisitos.

(h) Para impresiones grandes en azul, el prof. E. C. Cleaves, de la Universidad de Cornell, usa, en lugar de un marco, un cilindro de madera cubierto con fieltro, y que gira sobre su eje. Sobre este cilindro se extienden el trazado y el papel sensibilizado por medio de un sistema de agarradoras apropiado, y se hace girar el cilindro á la luz del sol. Este método evita el uso del vidrio. Necesita, naturalmente, mayor exposición que el método común. (*Trans. Am. Soc. Mech. Eng.*, vol. VIII, pág. 722.)

(i) Para impresiones aún mayores, el profesor R. H. Thurston extiende los dos papeles sobre una tabla delgada, la cual se cimbra y se mantiene en esa posición, sosteniendo así los papeles distendidos sobre el lado convexo. Por este método también se prescinde del vidrio, y como la curvatura de la tabla y los papeles es ligera, todo el papel queda expuesto á la vez á la luz. (*Trans. Am. Soc. Mech. Eng.*, vol. IX, pág. 696.)

**Art. 14.** (a) **El tiempo que se requiere para la exposición** varía según el color, la dirección é intensidad de la luz, de la opacidad y grueso del papel de calcar, de la negrura del dibujo, de los materiales, del esmero que se haya tenido en la sensibilización del papel y de la frescura de éste; desde dos ó tres minutos hasta horas y aun días. Aproximadamente se puede decir que en plena luz solar, en Filadelfia, unos tres minutos bastan generalmente desde el mediodía hasta las 2 p. m. y 10 minutos á las 10 a. m. ó las 4 p. m.; en la sombra, 13 á 40 minutos, á mediodía; pero no se puede establecer regla fija. La práctica debe decidir en cada caso. Si el respaldo del marco está dividido en dos ó más partes, se puede examinar el proceso de tiempo en tiempo.

(b) Si se ha hecho buen uso de una tinta perfectamente opaca, se puede imprimir el fondo de un azul muy obscuro; pero el exceso de exposición para la impresión hace el fondo negruzco y luego adquiere un tinte sucio. (Véase art. 17 c y d). Los trazados en tinta pálida deben imprimirse muy suavemente, á fin de que las líneas puedan permanecer blancas, y sería conveniente emplear para ellas una luz débil ó protegerlas con papel de seda ó un vidro esmerilado. (Véase art. 18 a.)

**Art. 15.** (a) Para obtener impresiones perfectamente claras, el lado del papel en que está el trazado debe estar en **perfecto contacto** con la superficie sensibilizada del papel, especialmente si, como sucede con la luz del sol, la dirección de la luz es variable; pues si alguna separación apreciable existe entre ellos, como cuando se imprime á través de cartón (véase art. 16 abajo), las sombras producidas por las líneas del trazado se mueven sobre la superficie sensibilizada según cambie la dirección de la luz, produciéndose una impresión borrosa. En la generalidad de los casos, sin embargo, es prácticamente imposible colocar de esta manera las dos superficies, pues esta posición da una impresión invertida con respecto á la derecha

ó izquierda *. Por consiguiente, se recomienda, en el art. 10 (a), el uso de un papel ó tela de calcar que sea delgado. Por la misma razón es imprescindible que los dos papeles estén firme y uniformemente comprimidos contra el vidrio.

**Art. 16.** (a) Empleando una luz de posición permanente con relación á la superficie del trazado, como una lámpara eléctrica de arco, es posible, prolongando la exposición por horas y aun días, obtener impresiones azules de **trazados hechos sobre papel grueso de dibujar**, y aun en una cartulina bristol (*bristol board*).

(b) Se puede lograr el mismo resultado con la luz del sol, ya sea colocando el original de espaldas al vidrio, y el papel sensibilizado (que debe ser muy delgado) de espaldas á la luz solar, ó colocando el marco de impresión en el fondo de una caja honda y angosta, de manera que la luz pueda caer directamente sobre el marco, sólo cuando esté aproximadamente en posición paralela á los costados más largos de la caja. Para imprimir rápidamente, se debe mantener la luz solar de lleno sobre el marco cambiando frecuentemente la posición de la caja.

**Art. 17.** (a) La impresión después de haber tenido suficiente exposición se quita del marco y se **lava muy bien** con agua limpia, por ambos lados, hasta que se desarrolla por completo el color azul característico.

(b) El lavado debe hacerse en una cubeta con el fondo plano, y que sea más grande que la mayor de las impresiones que se van á lavar; debe tenerse cuidado de no dañar la superficie de las impresiones frotándolas muy duro, ó por dobleces muy marcados.

(c) Se puede hacer el lavado más rápidamente, y también aclarar algo las impresiones muy obscuras ó « demasiado expuestas » empleando agua caliente, de 32° á 38° C.

(d) También se pueden aclarar las impresiones obscurecidas por demasiada exposición sumergiéndolas en agua, ligeramente alcalina, con amoníaco. En este baño adquieren un tinte purpúreo que á poco se debilita. En el momento preciso, que sólo se aprende en la práctica, se debe detener la acción alcalina pasando rápidamente la impresión por una solución de 1 parte de ácido hidroclórico (« muriático ») (H. Cl.) en 100 de agua.

(e) Continúese el lavado hasta que el agua quede enteramente clara y cuélguese la impresión bien extendida para que se seque.

**Art. 18.** (a) Después del lavado, la aplicación de una solución de 1 á 5 por ciento de ácido hidroclórico, ó ácido oxálico, en agua, intensifica el color azul, y por consiguiente hace más visible las impresiones pálidas ó que no hayan tenido suficiente exposición; pero éstas deben volverse á lavar después en agua pura. El ácido hidroclórico aplicado *antes* del lavado, ó á impresiones lavadas imperfectamente, hace que las *líneas* aparezcan azules.

**Art. 19.** (a) **Para borrar** una línea (blanca) en una impresión azul, repásese la línea con la solución sensibilizadora empleando para ello un pincel limpio ó una **pluma de ave**. Esto debe hacerse á una luz débil y luego se debe exponer de nuevo toda la impresión y volver á lavar.

(b) **Se agregan líneas blancas** á las impresiones azules generalmente con blanco de China; pero antes se debe quitar el color azul hasta que se vea el blanco del papel, por medio de una solución saturada de lejía concentrada (soda cáustica ó potasa) ó de carbonato de soda **, ó carbonato de potasa, aplicada con una pluma limpia y fina, casi seca. Si se aplica demasiada cantidad, se esparce muy rápidamente. Aun cuando la pluma esté perfectamente limpia, la superficie adquiere un tinte amarillento comparado con el blanco del papel. Las soluciones de carbonato obran más despacio que la lejía, pero no son menos seguras, y no dañan la superficie, mientras que la lejía quema mucho. El agua de cal vendida por los boticarios hace poca ó ninguna impresión sobre el color azul. Si se desean **líneas rojas en vez de blancas**, mézclese con la solución de soda ó de potasa tinta común de escribir color carmín, en la cantidad que dé el color deseado; ésta se fija por tanteos.

**Art. 20.** (a) Las impresiones azules que hayan de someterse á mucho uso deben **montarse** en tela, ó hacerse la impresión desde el principio en tela de calcar sensibilizada.

**Art. 21.** (a) **Los procedimientos que dan un fondo blanco**, con líneas azules ó negras, son generalmente tan complicados que están fuera del alcance de la

---

* Una impresión así invertida, puede, por supuesto, leerse fácilmente en un espejo. Esto se hace generalmente con los dibujos de la Oficina de Patentes.

** El mismo resultado da el carbonato (« soda de lavar ») que el bicarbonato.

mayor parte de los ingenieros. Sus resultados son, también, inseguros, aun hechos por expertos, pues á menudo queda el fondo poco blanco.

(b) **El papel Vandyke** (de Eugene Dietzgen Co, de Chicago) y el **Maduro**, dan excelentes **líneas color pardo** en papel bueno, liso y duro. El « Nigrosine » y otros llamados de impresiones negras, dan generalmente líneas purpúreas efímeras sobre un fondo gris, algo brillante, en un papel quebradizo, que no dura.

(c) **El procedimiento Le Clère** da excelentes impresiones en **líneas negras**. Las líneas son perfectamente negras y permanentes, y las impresiones se hacen en un papel de dibujo bueno, cuyo color y duración no se afectan por el procedimiento. También da bellas líneas azules en papel semejante al anterior.

# EXPLOSIVOS MODERNOS

**Art. 1. La mayor parte de los explosivos** que durante los últimos años han reemplazado á la pólvora, se componen de una substancia en estado de polvo, saturada parcialmente de nitroglicerina, que es un fluido producido por la mezcla de la glicerina con ácidos nítrico y sulfúrico.

**Art. 2. La nitroglicerina** pura, á 15°5 C, tiene un peso específico de 1.6. Es inodora, casi ó enteramente incolora, y tiene un gusto dulce y acre. Es venenosa, aun en muy pequeñas cantidades, y su manejo puede producir dolores de cabeza. Es insoluble en el agua. Se inflama á unos 152° C, y no estando encerrada arde sin producir explosión; á menos que sea en tal cantidad que alguna parte de ella, antes de ponerse en contacto con el aire, se caliente hasta el punto de producirla, la cual se efectúa próximamente á los 193° C.

La nitroglicerina y los polvos que la contienen **estallan siempre por medio** de una percusión aguda. Véanse arts. 36, etc. Después de hecha la nitroglicerina se requiere mucho cuidado para despojarla completamente de los ácidos sobrantes que le quedan al prepararla. La presencia de estos ácidos en la nitroglicerina líquida, ó en los polvos que la contienen, la hacen susceptible de descomposición espontánea, la cual por el alza de la temperatura aumenta el peligro de la explosión.

**Art. 3. La N-G se hiela** á 7°2 C, más ó menos. En este estado es **muy difícil la explosión** y debe deshelarse **gradualmente**, dejándola por tiempo suficiente en una habitación que tenga un calor moderado, ó poniendo el envase que la con-

tiene dentro de un segundo envase que contenga agua caliente á no más de 38° C; pero nunca debe exponerse á un calor intenso, tal como colocándola delante del fuego, ó sobre una estufa ó caldera. Se hacen fulminantes extrafuertes para estallar la nitroglicerina y sus polvos cuando está helada.

**Art. 4. La N-G**, debido á su incompresibilidad, está **expuesta á explosiones por percusiones accidentales**. Esta circunstancia, y la facilidad que tiene para filtrarse, la hacen poco á propósito para su transporte y manejo. Por lo que rara vez se usa en su estado líquido en las canteras y otros lugares donde haya que aplicar explosivos. En las regiones petrolíferas de Pensilvania se usa mucho **en los pozos de petróleo** para aumentar la descarga. Con este objeto se mete en tubos cilíndricos de hojalata, de 2½ á 12 cm de diámetro, llamados bombas de torpedo. Éstas se suspenden y se bajan al pozo por medio de una cuerda ó alambre arrollado en un carrete y se destruyen al estallar la carga. Tienen 2½ cm menos de diámetro que la perforación del pozo y contienen de 1 á 20 lit, ó sea de 2.30 á 30 kg de N-G. Su extremo inferior es puntiagudo para facilitar su paso á través del petróleo ó agua que pueda contener el pozo. Cuando se requiere una carga mayor de 30 kg, se colocan dos ó más de estas bombas en el pozo, una sobre la otra, de manera que la punta inferior cónica de cada una de ellas ajuste la parte superior de la siguiente. En este caso se hace estallar la nitroglicerina por medio de uno ó varios fulminantes colocados en la parte superior de la carga antes de bajarla al pozo. Cuando la carga está en su lugar, se hacen estallar los fulminantes por medio de la electricidad comunicada por alambres conductores, como en el art. 37, ó (según el método más usado) dejando caer un peso sobre ellos.

Cuando en un pozo han estallado varios torpedos, y de este modo se ha formado una cavidad tan grande que el espacio que rodea al torpedo disminuye los efectos de la explosión sobre las paredes del pozo, entonces se coloca directamente la N-G en el pozo, bajando un cilindro lleno de ella, provisto de una disposición automática que permite su salida cuando llega el cilindro al fondo del pozo, y se la hace estallar por medio de un torpedo suspendido de una cuerda y provisto de cápsulas fulminantes colocadas en su parte superior. Estas cápsulas se hacen estallar por medio de la electricidad, ó deslizando hacia abajo, por la cuerda, pesos de plomo ó de hierro. Cuando la roca se compone de vetas ó filones, se encierra la N-G en envases cilíndricos cortos de hojalata, que se bajan á la cavidad y se hacen estallar por medio de un torpedo. La nitroglicerina se emplea también para aumentar la corriente de los manantiales de agua. Se comprende naturalmente que aquélla no puede usarse en perforaciones **horizontales ó inclinadas** hacia arriba, como las que se hacen en los túneles, etc.

**Art. 5.** La nitroglicerina hace explosión tan de repente que **no es necesario atacar mucho la carga**. La tierra ó la arena mojada, ó aun el agua, bastan al efecto. Esta circunstancia y el hecho de que no la afecta el agua y de que es más pesada que ella, la hacen particularmente **útil para obras debajo del agua**, ó para perforaciones que contienen agua, con tal de que la roca no tenga grietas que permitan el escape de la N-G. Cuando la roca está **compuesta de vetas ó filones**, debe encerrársela herméticamente en cilindros; estos cilindros ó cajas, sin embargo, dejan necesariamente algún espacio entre la roca y el explosivo, lo cual disminuye considerablemente el efecto de este último.

**Art. 6. La gran fuerza explosiva de la nitroglicerina** se debe en parte al volumen muy grande de gas en que se convierte, por la explosión, una pequeña cantidad de ella, y en parte á la rapidez con que se efectúa aquella conversión, de modo que los gases se ponen en libertad casi instantáneamente, mientras que con la pólvora la producción de los gases se efectúa en mayor tiempo. La acción repentina de la explosión aumenta el efecto, no solamente porque aplica toda su fuerza en un instante, sino también porque se calientan mucho los gases producidos y aumentan así considerablemente su volumen.

**Art. 7.** El estado líquido de la nitroglicerina es conveniente, por que **permite llenar completamente la perforación**, de modo que no queden espacios vacíos con los cuales se disminuye la fuerza de la explosión. Por otra parte, la forma líquida tiene también su desventaja, porque cuando se usa sin envase en rocas estratificadas, parte de ella se filtra y se queda sin hacer explosión y hasta sin notarse, pudiendo más tarde causar una explosión accidental.

**Art. 8. La N-G se guarda en envase de hojalata ó de loza.** Si está bien limpia de ácidos, no daña á la hojalata. Para su transporte, estos envases se embalan en cajas con aserrín, ó en cajas forradas por dentro, y éstas se cargan en carretas. Los ferrocarriles no las reciben como flete.

**Art. 9.** Cuando la N-G y sus componentes han hecho explosión **completamente, los gases resultantes** no son molestos, pero los que provienen de una explosión **incompleta**, como generalmente resulta, ó de la combustión, son muy dañinos.

**Art. 10.** Por conveniencia, damos el nombre de « **dinamita** » á cualquier explosivo que contenga N-G mezclada con un absorbente granular; de « **dinamita verdadera** » á aquella en que el absorbente de la nitroglicerina sea « Kieselguhr » * ú otro polvo **inerte** que no toma parte alguna en la explosión; y de « **dinamita falsa** » á aquellas en las cuales el absorbente mismo contiene otros explosivos que no sea N-G.

**Art. 11. El absorbente**, por su condición compresible, y granular, **obra como cojín**, resorte protector (*cushion*), de la N-G y la defiende de las percusiones y del peligro consiguiente á una explosión accidental.

La N-G no cambia su naturaleza porque sea absorbida : se hiela, arde, estalla, bajo las mismas condiciones de presión, temperatura, etc., que cuando está en forma líquida. El efecto de **cojín** ó defensa del absorbente sólo aumenta la dificultad de producir la presión suficiente para causar la explosión. La absorción de la N-G en la dinamita hace á ésta apta para ser usada en perforaciones **horizontales**, ó inclinadas hacia **arriba**.

**Art. 12.** La N-G y la dinamita hacen explosión mucho más ligero cuando están limitadas por una materia rígida como en un envase **metálico**, ó por las paredes de una perforación hecha en la roca, que cuando están encerradas en una substancia **que cede**, como la madera. Por lo tanto, el hecho de que la dinamita, no siendo líquida, puede embalarse en cajas de madera, la hace menos peligrosa que la N-G, la cual debe guardarse en envases de loza ó metal.

**Art. 13. La dinamita verdadera debe contener por lo menos 50 por ciento** de nitroglicerina. De no ser así, el absorbente la protegería demasiado y sería muy difícil hacerla estallar. Las dinamitas falsas, al contrario, pueden contener un tanto por ciento tan pequeño de N-G como se desee; algunas de ellas no contienen sino 15%. Las substancias explosivas que se agregan en la falsa dinamita contienen grandes cantidades de oxígeno, que se desprende con la explosión, y contribuye á efectuar la combustión completa de los gases nocivos.

**Art. 14. Las dinamitas que contienen un tanto por ciento grande de N-G** estallan (como la N-G líquida, art. 6) muy repentinamente, con tendencia á destrozar ó romper en pedazos pequeños la roca cercana. Son las más útiles en la roca muy dura; la **dinamita n.º 1**, ó la que contiene 75 por ciento de N-G, se considera que, en esta clase de roca, **tiene más ó menos 6 veces la fuerza de un peso igual de pólvora de cañón.**

**Para rocas blandas ó descompuestas**, arena y tierra, **las clases menos fuertes** de dinamita, ó las que contienen un percentaje menor de N-G, son las más á propósito. Hacen explosión con menos rapidez, y su tendencia es más bien á levantar grandes masas de roca que á fracturar pequeñas masas de ella. Por esto, se parecen más bien en su acción á la pólvora de cañón.

Debe calcularse con discreción, en cada caso, la **calidad y cantidad** del explosivo que ha de usarse. Cuando no haya inconveniente en fracturar la roca en pedazos pequeños, ó cuando se desea hacerlo así para mayor facilidad del acarreo, es más útil emplear las más fuertes y destructivas. Cuando se quiere sacar la roca en grandes masas, como en las canteras, son preferibles las menos fuertes.

Para trabajos difíciles en roca dura, y para explosiones submarinas, se usan las calidades más fuertes, que contienen de 70 á 75 por ciento de N-G. Una pequeña carga de ésta produce el mismo efecto que una carga grande de la clase menos fuerte y, por supuesto, no requiere una perforación tan grande.

En los trabajos submarinos la explosión rápida no es disminuída por el agua.

Para trabajos comunes de ferrocarriles ó para perforaciones ordinarias de túneles, excavaciones de minas de minerales, se emplea la clase mediana que contiene 40% de N-G; en las canteras, una que contenga 35%; para volar troncos, árboles, estacas, etc., 30%, y para arena y tierra, 15%.

**Art. 15.** La dinamita, lo mismo que la N-G, **puede hacerse estallar fácilmente debajo del agua** con tal que esté sumergida de manera que no pueda **esparcirse; pero una permanencia prolongada en el agua la daña.**

---

* « Kieselguhr » es una piedra calcárea silícica terrosa, compuesta de los restos fósiles de pequeñas conchas. Cada conchita obra como un receptáculo minúsculo para la nitroglicerina. Kieselguhr se encuentra en Hanóver (Alemania) y en New Jersey.

En las clases más fuertes, el agua, por su mayor afinidad con el absorbente, expulsa la N-G. En las clases inferiores el agua puede disolver las sales empleadas como explosivos adicionales.

**Art. 16.** En las dinamitas que contienen un tanto por ciento elevado de N-G, esta última está expuesta á rezumarse ó á filtrarse, sobre todo en época de calores, y á estallar por cualquiera percusión accidental. Existe el mismo peligro, aun cuando el tanto por ciento de la nitroglicerina sea pequeño, si el absorbente no tiene sino un pequeño poder de absorción y por consiguiente se satura fácilmente.

**Art. 17. La dinamita verdadera** se parece al azúcar moscabado. Sus **propiedades** son generalmente las de la N-G que contiene. De manera que arde á 177° C más ó menos y quema libremente. Se hiela á 7°2 C y entonces es difícil hacerla estallar. No hace explosión por el frotamiento ó por percusión ordinaria; requiere en trabajos comunes una cápsula fuerte ó detonador, que contenga pólvora fulminante (véanse arts. 36, 38, etc.). Puede, sin embargo, estallarse con una mecha de pólvora de cañón, atacada fuertemente y encendida por medio de una mecha de seguridad.

**Art. 18. La carga debe llenar la sección transversal de la perforación** tan completamente como sea posible. Si no hay agua dentro del agujero, debe hacerse al cartucho una incisión antes de colocarlo, de modo que el polvo pueda salir y llenar la perforación, ó simplemente vaciarlo.

**Art. 19. Para volar el hielo** en su propio lugar, se abren en él orificios, se ata un número de cartuchos de dinamita (uno de ellos provisto de su cápsula fulminante) y se hacen descender de .30 á 1.50 m dentro del agua. Se hacen estallar tan pronto como sea posible después de la inmersión, para evitar el peligro de que se hielen. Las detonadoras eléctricas (art. 37, etc.) son las mejores para obras debajo del agua.

**Art. 20.** La dinamita es útil para **quebrar piezas** de metal, como cañones viejos, maquinarias desechadas, « salamandras » (masas de escoria endurecida) de hornos de fundición, etc. En los cañones, naturalmente, la dinamita hace explosión en el alma. En otras piezas se hacen generalmente pequeños agujeros para introducirla; pero las planchas de metal, aun de un espesor considerable, pueden romperse, haciendo simplemente estallar la dinamita sobre su superficie.

**Art. 21. Para volar árboles ó troncones**, se hacen estallar uno ó más cartuchos en un orificio practicado en el tronco ó raíz ó debajo de esta última. Así estalla el tronco y las raíces. Puede tumbarse un árbol practicando dentro de él perforaciones de pequeño radio á distancias cortas é iguales en una línea horizontal alrededor de su circunferencia y por medio de una batería eléctrica (arts. 37, etc.) que haga estallar simultáneamente una pequeña carga de dinamita en cada taladro hecho. En un árbol pequeño basta amarrar un solo cartucho largo alrededor del tronco y hacerlo estallar.

**Art. 22. Las estacas pueden volarse del mismo modo que los árboles**; puede también hacerse una perforación en el eje para alojar el cartucho, ó éste puede simplemente amarrarse á cualquiera altura.

**Art. 23.** Las clases superiores de dinamita, lo mismo que la nitroglicerina, **no es preciso que se ataquen mucho.** Usese siempre una **barra de atacar de madera, nunca de metal**, para cualquiera explosivo. Es peligroso sacar una carga de dinamita que « arde lentamente » sin estallar. Sáquesele casi todo el **taco**, dejando sólo algunos cm de grueso encima de la carga; sobre ésta colóquese otro cartucho que contenga el detonador, y hágase la prueba nuevamente. Véase detonadores eléctricos, arts. 37, etc. Si la dinamita está helada, lo mismo que la N-G, entonces debe deshelarse *gradualmente*, dejándola en un cuarto caliente, lejos del fuego, ó colocándola en un envase metálico que luego se coloca dentro de otro envase que contenga agua caliente. El agua no debe estar más caliente de lo que pueda soportar la mano. De lo contrario la N-G puede separarse del absorbente. La N-G contenida en la dinamita puede helarse sin pegarse ó unirse á las moléculas del absorbente, en cuyo caso el polvo es blando al tacto. Una **carga excesiva** de N-G ó de dinamita está expuesta á quemarse y de este modo á desperdiciarse, dando salida á gases nocivos.

**Art. 24. La dinamita se vende en cartuchos cilíndricos, cubiertos de papel**, de 20 á 50 mm de diámetro y de 15 á 20 cm ó más de largo. Se suministran de cualquier tamaño, según pedidos, y están embalados en cajas que contienen 25 ó 50 lbs (11.3 á 22.6 kg) cada una. Las hileras de cartuchos están separadas por aserrín.

**Art. 25.** Algunas **Compañías de ferrocarriles** se niegan á transportar nitroglicerina ó dinamita en cualquier forma. Otras llevan dinamita bajo ciertas

restricciones, basadas sobre leyes de Estado; exigiendo que esté seca (es decir, que no esté filtrando ó sudando nitroglicerina); que las cajas y los carros que la contienen deben marcarse claramente con algunas palabras de precaución, como « explosivos », « peligroso », etc; que los cartuchos estén empaquetados de tal modo en las cajas y éstas colocadas en los carros de tal manera, que ambos descansen sobre sus costados y que no haya peligro de que las cajas se volteen dentro del carro; que las cápsulas fulminantes, etc., no se lleven en el mismo carro junto con la dinamita, etc.

**Art. 26. Se fabrica una gran variedad de clases de dinamita.** Varían (en general muy poco) en la composición del absorbente y en el modo de fabricación. Cada fabricante hace generalmente un número de clases que contienen tantos por ciento diferentes de nitroglicerina, etc., dando á sus polvos un nombre de fantasía.

**Art. 27.** La siguiente **tabla de explosivos** hecha por « The Repauno Chemical Company, Thompson's Point, N. J., Office Wilmington, Delaware », y conocida bajo el nombre de « **Atlas** » **powders** (pólvoras « Atlas »), da el tanto por ciento de N-G que entra en cada una de ellas.

| Marca. | Tanto por ciento de nitroglicerina. | Marca. | Tanto por ciento de nitroglicerina. |
|---|---|---|---|
| A | 75 | D+ | 33 |
| B+ | 60 | | |
| B | 50 | E+ | 27 |
| C+ | 45 | E | 20 |
| C | 40 | | |

**Los absorbentes contienen** en la marca « A » 18 por ciento de pulpa de madera y 7 por ciento de carbonato de magnesia; en la marca « C » (clase media), 46 por ciento de nitrato de soda (soda y sal de nitro), 11 por ciento de pulpa de madera y 3 por ciento de carbonato de magnesia; en la marca « E », 62 por ciento de nitrato de soda, 16 por ciento de pulpa de madera, etc., y 2 por ciento de carbonato de magnesia.

**Art. 28. La pólvora « Miner's Friend »** (Amiga del Minero), contiene nitrato de soda, pulpa de madera, resina y carbonato de magnesia. Se hiela á 5°5 C, y es, entonces, como otras dinamitas, difícil para estallar. Cuando se usa debajo del agua, no deben romperse los cartuchos, porque los ingredientes sufren con el contacto directo del agua. La pólvora « Hecla » es de clase inferior. Es de forma granulada, lo mismo que la pólvora ordinaria de barrenos; pero se dice que es más fuerte. Se emplea como un sustituto de la pólvora ordinaria.

**Art. 29. La pólvora « Giant »** (Gigante) es propiamente una dinamita, y contiene 75 por ciento de nitroglicerina y 25 por ciento de Kieselguhr (tierra de conchas fósiles) obtenida cerca de la fábrica en New Jersey. La clase más baja, marca « M », contiene 20 por ciento de nitroglicerina. Se daba originalmente el nombre de « pólvora gigante » á la dinamita en general.

**Art. 30.** Hay otras marcas, á saber: « Pólvora de Hércules », y « Pólvora R.R.P. de Judson », que reemplaza la pólvora ordinaria de barreno. Está empaquetada en sacos impermeables de papel de 6¼, 12½ y 25 libras (2.83, 5.66 y 11.34 kg) cada uno, y éstos están embalados en cajas de madera que contienen 50 lbs (22.6 kg) cada una. La **dinamita Judson F.F.F.** es de calidad superior, viene en cartuchos de forma usual, en cajas de á 50 lbs (22.6 kg).

**Art. 31.** Los cartuchos de « **Rackarock** » se dice que no contienen nitroglicerina y que son enteramente inexplosivos, hasta que se les sumerge, por algunos segundos, en un líquido inexplosivo suministrado por los fabricantes. Al sacarlos del líquido se dejan parados 15 minutos, después de los cuales se pueden usar en cualquier tiempo. Se encienden lo mismo que la dinamita y pueden usarse debajo del agua. Los fabricantes sostienen que Rackarock « se aproxima en fuerza á la nitroglicerina, y que es más fuerte que la dinamita ».

**Art. 32. Los siguientes explosivos se fabrican y se usan en Europa,** pero no han sido importados todavía con regularidad á los Estados Unidos.

**El algodón pólvora comprimido** es un algodón sumergido en una mezcla de ácidos nítrico y sulfúrico, luego reducido á una pulpa fina; se le da la forma de

discos de 2½ á 5 cm de grueso y de 2 á 5 cm de diámetro, ó más grandes. Generalmente se emplea mojado, para mayor seguridad. En este estado requiere fulminantes bastante fuertes. Hablando en general, es casi tan fuerte como la dinamita n.° 1, pero su efecto es menos *desgarrador*. Como es menos pesado que la dinamita, requiere perforaciones más grandes; y debido á su rigidez, no puede colocarse tan fácilmente, y no se adapta tan completamente á la perforación. Seco es muy inflamable; pero no estando encerrado, arde sin peligro. No contiene líquido y por lo tanto no se hiela ni exuda y su manejo no es peligroso.

**Art. 33. La Tonita** se compone de algodón pólvora dividido finamente, mezclado con nitrato de barita. Está comprimida en cartuchos en forma de velas, que tienen en un extremo un espacio para recibir un detonador con fulminante de mercurio. Los cartuchos pesan más ó menos lo mismo que la dinamita, y generalmente se hacen impermeables.

**Art. 34. Forcite, Lithofractor y Dualin** son productos extranjeros de explosivos de nitroglicerina. En el Dualin el absorbente consiste en aserrín. Presenta un volumen mayor que la dinamita y requiere perforaciones más grandes.

**Art. 35. La gelatina explosiva** es una substancia transparente de color amarillo pálido y elástica, y está compuesta de 90 por ciento de nitroglicerina y 10 por ciento de algodón pólvora. Es menos sensible á la percusión, fricción ó compresión que la dinamita y no la afecta el agua. Su peso específico es 1.6; arde al aire libre. Para su completa explosión se requiere un fulminante especial. La adición de una pequeña cantidad de alcanfor la hace menos sensible todavía y aumenta su fuerza explosiva. El alcanfor se evapora en cierto grado.

En algunos experimentos hechos sobre la fuerza de diferentes explosivos para aumentar la capacidad de una pequeña cavidad practicada en un pedazo de plomo, la gelatina explosiva produjo un aumento 50% mayor que el causado por la dinamita n.° 1. En roca dura la diferencia hubiera sido probablemente mayor. El aumento fué un 10% menor que el causado por la nitroglicerina.

**Art. 36. La cápsula fulminante, ó detonador,** usada con la mecha de seguridad ordinaria para estallar la nitroglicerina y la dinamita, es un cilindro hueco de cobre, de más ó menos 6 mm de diámetro y de 25 á 50 mm de largo. Contiene de 15 á 20%, ó más, de fulminante de mercurio, mezclado con otros ingredientes y hecho un cemento, que llena la parte cerrada de la cápsula. Se dice que las cápsulas son de « fuerza sencilla », « fuerza triple », etc., según la cantidad del explosivo que contienen.

La punta de la mecha, cortada á escuadra, se inserta en la extremidad abierta del fulminante, á suficiente profundidad para que toque la mixtura que contiene. Al hacer esto debe tenerse cuidado de no rozar esta última. El cuello de la cápsula se aprieta cerca de la extremidad abierta, para sujetar bien la mecha. La cápsula, con la mecha fija de este modo, se mete entre la carga de nitroglicerina, ó dinamita, teniendo cuidado de que la mecha no se ponga en contacto con el explosivo, porque éste se quemaría y se inutilizaría. Si se usa un cartucho de dinamita, se coloca primero la mecha con su cápsula. La parte superior ó cuello del cartucho se amarra con una cuerda alrededor de la mecha y de este modo está ya listo para colocarlo en la perforación y estallarlo.

**Art. 37. La caja electromagnética de Siemens,** hoy en uso general, se compone de una caja de madera del tamaño de una caja de teodolito. En el exterior tiene dos postes metálicos con tornillos para la conexión de los dos alambres que conducen al detonador. De la parte superior de la caja sobresale un mango con la punta de una barra vertical. Esta barra, más ó menos tan larga como alta es la caja, está construída de manera que se deslice en ella hacia arriba y hacia abajo, y está provista de una cremallera que engrana en un pequeño piñón en el interior de la caja. Cuando se va á prender el barreno, se tira de la barra hacia arriba por el mango hasta donde puede llegar, luego se aprieta hacia abajo con rapidez, hasta el fondo de la caja. En su descenso, pone en acción, por medio del piñón, una máquina electromagnética que se encuentra en el interior de la caja. Ésta produce una corriente eléctrica que aumenta en intensidad con el movimiento de la barra hacia abajo, pero que está limitada á un corto circuito del alambre dentro de la caja, hasta que el extremo inferior de la barra toca un resorte situado cerca del fondo de la caja, el cual rompe el corto circuito y obliga á la corriente á pasar por los dos alambres conductores que la llevan de los dos postes del exterior de la caja á la cápsula fulminante ó detonador colocado en la carga.

**Art. 38. La cápsula** que se usa en esta máquina es semejante á la usada con la mecha de seguridad (art. 36), con la diferencia de que ésta tiene el fondo cerrado con un cemento de azufre por el cual pasan los alambres conductores de la máquina

eléctrica. Los extremos de estos alambres entran en la mezcla fulminante de la cápsula. Tienen una separación de 3 mm; pero están conectados por un alambre de platino tan delgado, que la corriente de la máquina lo calienta hasta el rojo; su calor enciende el fulminante y hace estallar la cápsula.

**Art. 39. Para hacer estallar simultáneamente un número de barrenos** (aumentando así su efecto), se coloca en cada uno de ellos una carga con su cápsula de platino, y uno de los alambres cortos, fijado á cada cápsula, se pone en conexión con uno de los de la próxima cápsula, de modo que en cada serie de cápsulas hay una punta libre de un alambre corto. Cada una de estas dos puntas se fija al extremo de uno de los alambres conductores, poniendo toda la serie « en circuito ». Cuando las perforaciones están demasiado separadas unas de otras para conectar las cápsulas, como se ha dicho por el alambre corto unido á ellas, las extremidades de este último se unen por un **alambre aislado**.

**Art. 40. La máquina electromagnética** pesa unos 7 kg. Puede hacer estallar unas 12 cápsulas simultáneamente.

Las cápsulas para las cebas ordinarias y para hacer estallar por la electricidad, los alambres, y, además, las máquinas eléctricas, etc., las venden la mayor parte de los que comercian en explosivos, máquinas de barrenar, etc.

**Art. 41.** Solamente por medio de la electricidad pueden inflamarse simultánea y convenientemente un número de perforaciones. El aparato eléctrico de estallar es especialmente útil para explosiones debajo del agua, donde la mecha ordinaria, sobre todo á grandes profundidades, está expuesta á humedecerse é inutilizarse.

Cuando una máquina eléctrica no logra inflamar la carga, se sabe que ésta ya no puede estallar hasta que no se repita la operación. Por lo tanto no hay que perder tiempo ni correr ningún riesgo.

## PÓLVORA DE CAÑÓN

La fuerza explosiva de la pólvora es de unos 2,800 kg por cm cuad. Su **peso** medio es más ó menos el del agua, ó sea 1 kg por litro. En los trabajos de cantera, un metro cúbico de roca maciza en su sitio original (ó m ó m 1.9 m cúb amontonada después de sacada de la cantera), requiere de 113 á 340 gramos. En rocas duras en exceso y mal situadas para sacarlas de la cantera, un metro cúb macizo puede requerir de 450 á 900 gramos. En algunas de las más grandes voladuras de roca y de más satisfactorios resultados, alcanzados en la construcción del Tajamar de Holyhead, en Wales (en que varios millares de libras de pólvora se hacían estallar generalmente por medio de la electricidad en una sola explosión), se **desprendieron** de 1.5 á 3 metros cúbicos macizos por cada libra de pólvora; pero en muchos casos no se volaron más de ¾ á 1½ m cúbs. En la construcción de túneles y pozos se requiere de 1 á 2½ kg por metro macizo; pero más generalmente de 1 ¼ á 2 ¼. La roca blanda, en parte descompuesta, requiere frecuentemente más que las duras. Se vende generalmente en cuñetes de 11.4 kg.

### Peso de la pólvora por 30 cm de profundidad de barreno.

(*N. del T.* — Hemos convertido la tabla del autor al sistema métrico.)

| | | | | | | |
|---|---|---|---|---|---|---|
| **Diám del barreno en mm** | 25 | 30 | 37 | 50 | 63 | 75 |
| **Peso de la pólvora en kg** | .142 | .227 | .312 | .567 | .907 | 1.276 |
| **Diám del barreno en mm** | 90 | 100 | 114 | 150 | 163 | 180 |
| **Peso de la pólvora en kg** | 1.758 | 2.268 | 2.892 | 3.572 | 4.309 | 5.131 |

# APUNTAMIENTOS SOBRE INGENIERÍA LEGAL

Por el doctor J.-L. ARISMENDI, abogado, miembro de la Academia de Ciencias Políticas y Sociales de Venezuela, de las Sociedades de Derecho Comparado, de Paris, de la Derecho Internacional, de Washington, del Instituto Ibero Americano de Derecho Comparado de Madrid y Catedrático de la Universidad de Caracas.

---

## Nota del Traductor.

Los ingenieros y jefes de obras en el estudio y construcción de éstas, son quizás entre todos los profesionales los que más necesitan conocer los preceptos del Derecho que se relacionan con el ejercicio de su profesión. Desde el emplazamiento de sus construcciones, durante la ejecución y luego en la explotación, están expuestos a vulnerar el derecho ajeno por la falta de conocimientos, siquiera generales y someros de aquellas prescripciones. Cuantos litigios han resultado de tales deficiencias.

Es por esto que hemos creido conducente y eficaz agregar en esta nueva edición las muy breves apuntaciones, excesivamente sintéticas, que ha tenido la bondad de suministrarnos el notable Jurisconsulto venezolano, Doctor José Loreto Arismendi, cuya ilustrada colaboración jurídica hemos solicitado y a quien reiteramos nuestra gratitud por su trabajo.

Los principios expuestos por el Doctor Arismendi están basados sobre el Derecho Francés, en atención a que éste es el que ha servido generalmente de modelo para calcar sus leyes las naciones de habla española.

Así como, por la índole de este Manual, no se entra en razonamientos y conexiones extensas constitutivos de un estudio completo de la técnica de la ingenieria dando solo las fórmulas y la exposición sintética de las teorías y principios, así también, en el apéndice jurídico de que tratamos, sólo se formulan mui brevemente algunos dictámenes que, íntimamente ligados con las materias de esta obra sirvan como de advertencias útiles para orientar y provocar consultas y más amplios estudios, cuando fuere necesario.

## Contrato de arrendamiento de obra.

Cuando un ingeniero, o cualquiera otra persona, según los casos, se encarga de hacer una obra para otro, puede convenirse en que preste únicamente su trabajo o su industria, o bien que, ademas de ésta, suministre tambien los materiales. — En el primer caso el contrato constituye, sin ninguna duda, un arrendamiento de obra puro y simple; pero, en el segundo, hay que distinguir, si la materia suministrada por el ingeniero es la parte principal y no un simple accesorio del trabajo porque, el contrato tiene entonces el carácter de una venta. Es arrendamiento de industria y no venta, el contrato por el cual un ingeniero se encarga de construir, aun suministrando sus propios materiales una obra sobre el terreno perteneciente al propietario para quien construye.

Las obligaciones del locador (que en este caso es el ingeniero) consisten :

*a*) Ejecutar la obra de que está encargado;

*b*) Terminarla en el plazo convenido, so pena de daños y perjuicios, a menos que el retardo no se deba a un caso de fuerza mayor o a un hecho del locatario;

*c*) A ejecutar las obras segun los principios de la Ciencia.

El locador puede ser condenado a hacer inmediatamente las refacciones necesarias debidamente comprobadas para que la obra quede libre de defectos y tenga las cualidades que requiere una buena ejecución de los trabajos.

El locador es responsable del hecho de las personas que emplea en la ejecución de la obra. El empresario responde especialmente del hecho de los sub-empresarios con los cuales ha contratado las diversas partes de la obra que está encargado de ejecutar.

El dueño (que en este caso es el conductor o locatario), es decir, aquel para quien se construye la obra, está obligado principalmente a pagar el precio convenido. Dicho precio puede determinarse, sea de una manera invariable por el conjunto de la obra, sea por medio de una cuenta detallada de los trabajos ejecutados con fijación del precio de cada artículo.

El ingeniero o empresario, no puede exigir, salvo convenio especial, el pago de la obra, sino cuando esté enteramente terminada; y, si estuviere defectuosa, despues de practicada la refacción necesaria para perfeccionarla. El tiene un privilegio para el pago de su crédito sobre el valor del inmueble, y está garantizado por un derecho de retención sobre el objeto del contrato.

Cuando se ha estipulado un precio fijo por la construcción de la obra, no puede el ingeniero o empresario exigir ningun aumento so pretexto de estar mas caros los materiales y la mano de obra, ni por cambio o aumentos hechos sobre el plano primitivo, no aprobados previamente por el propietario del suelo.

## Trabajos públicos.

Se entiende por trabajos públicos los que son emprendidos con un fin de interés general por el Estado o por alguna persona moral que le esté asimilada, sobre este punto, por la ley o la jurisprudencia. Tales son los trabajos de construcción, modificación, reparación y conservación de los caminos, puertos, canales, rios navegables, ferrocarriles, lineas telegráficas, fortificaciones, establecimientos militares, etc.

Los trabajos ejecutados por los empresarios o concesionarios subrogados en los derechos de la Administración, tienen el mismo carácter que si fueran ejecutados por ella misma. Asi los trabajos ejecutados por las compañias concesionarias de ferrocariles, teniendo por objeto la creación o conservación de las vias férreas y de sus anexos, son trabajos públicos.

**La ejecución de los trabajos públicos** necesita la formación previa de planos y presupuestos, sucesivamente aprobados, desde el punto de vista técnico, por la autoridad competente, segun que se trate de trabajos del Estado, de los departamentos, de las comunas o de los establecimientos públicos. Es menester luego que los trabajos sean regularmente autorizados.

Caso de que, para la ejecución de los trabajos se necesite disponer de la propiedad privada, debe procederse a la expropiación, por causa de utilidad pública, de acuerdo con la ley.

El contrato de trabajos tiene el carácter de arrendamiento de obra, por el cual un ingeniero o empresario se obliga a ejecutar ciertos trabajos mediante un precio determinado. Son necesarios los documentos o piezas siguientes :

*a*) Planos y presupuestos; *b*) Pliego de condiciones con la descripción detallada

de los trabajos; *c*) Resumen de cuentas indicando el precio que debe pagarse por cada unidad de medida de los diferentes trabajos por ejecutar; *d*) Detalle estimativo de los gastos para la ejecución de los trabajos descritos en el presupuesto; *e*) Avalúo de la cantidad de cada naturaleza de obra y el volumen aproximado.

Los trabajos públicos pueden ser ejecutados por la Administración directamente, o bien por vía de concesión o por contrato. Todos los tratos para trabajos del Estado en la forma de adjudicación pública o de convenciones, están sometidos a las condiciones establecidas en el Memorial de los trabajos.

**Obligaciones relativas a los materiales.** — Los materiales para las construcciones deben ser de buena calidad y consistencia conforme a las reglas de la Ciencia. El empleo de éllos debe ser precedido de una verificación y aceptación por el ingeniero en Jefe o por sus encargados, y, la recepción de los materiales, hace fe de la buena calidad de éstos, hasta prueba en contrario.

Los materiales malos o defectuosos pueden ser rechazados y dejarse por cuenta del Empresario, quien no puede reclamar su valor ni los gastos de transporte.

Si ya han sido empleados los materiales, no obstante su mala calidad, pueden hacerse demoler por el Empresario las construcciones en que hayan entrado para reemplazarlos por otros de buena calidad que él mismo debe suministrar.

El empresario no puede hacer ningun cambio en los proyectos, y debe inmediatamente reemplazar, por orden del ingeniero, los materiales o reconstruir las obras cuyas dimensiones o disposiciones no sean conformes al Presupuesto o a las órdenes del servicio. Sin embargo, los ingenieros pueden conservar los trabajos verificados, sin que el empresario tenga derecho, en este caso, a ningún aumento de precio en razón de las dimensiones mas fuertes o de mayor valor de los materiales. Al contrario cuando estas dimensiones sean mas débiles, debe sufrir una disminución de precio, a menos que la Administración haya hecho imposibles las verificaciones a las cuales el empresario tenia derecho, segun el presupuesto, o que los materiales no hayan sido empleados por órden del ingeniero.

**Plazo para la ejecución de los trabajos.** — El empresario debe ejecutar los trabajos dentro del plazo convenido, y, en defecto de cláusula expresa sobre este punto, dentro de un plazo proporcional a la naturaleza e importancia de la obra.

Las cláusulas penales establecidas a este respecto en la contrata o pliego de cargas, no pueden ser aplicadas al empresario sino cuando el retardo proviene de su falta, y no cuando es imputable a la Administración o a las dificultades excepcionales que no habian podido preverse.

**Fijación de precios.** — El empresario puede pedir un precio mas elevado del convenido, siempre que en virtud de las órdenes recibidas en el servicio se haya aumetando el volumen de los trabajos, agravándose para él las condiciones estipuladas; pero si ningun precio ha sido indicado previamente para una obra imprevista o por cambios verificados en las obras previstas para variar la naturaleza de éstas, el ingeniero o empresario tiene el derecho de hacer fijar un precio especial, segun el de las obras análogas.

**Obligaciones relativas a los obreros.** — El empresario debe tomar por empleados y jefes de talleres hombres capaces de ayudarlo y reemplazarlo en caso de necesidad en la conducción de los trabajos. El ingeniero tiene sobre este personal y sobre los obreros un derecho de *control*.

El empresario tiene algunas obligaciones relativas al número de los obreros que debe conservar en los talleres, a la policía de los trabajos, al pago periódico de los salarios, etc., y está sometido a la responsabilidad de los accidentes sobrevenidos a los obreros en la ejecución de los trabajos.

**Modificación en los trabajos.** — La Administración, contrariamente al derecho común, puede, por motivos de interés general, hacer algunas modificaciones a los trabajos en ejecución. Estas modificaciones pueden consistir en un aumento o disminución del volumen de los trabajos, o en un cambio en cuanto a la importancia de ciertas obras o en la ejecución de otras nuevas.

En los trabajos de puentes y calzadas, si el aumento no excede de la sexta parte del montante de la obra, el empresario puede solamente reclamar el montante de los trabajos suplementarios; pero, si excede, tiene el derecho a rescindir el contrato sin indemnización. El aumento del sexto se calcula, segun los precios del presupuesto, sin tener en cuenta las rebajas, así como tampoco el precio de trabajos que hayan sido el objeto de un contrato distinto.

La rescisión debe ser demandada dentro de los dos meses siguientes a la notificación de la orden de servicio al empresario que es el que tiene ese derecho. La Administración no puede prevalerse del aumento de mas de un sexto para confiar una parte de los trabajos a otro; ella debe en este caso indemnizar al empresario. Rescindido el contrato, el Estado, si lo juzga util, puede adquirir el material, pero el empresario no puede obligarlo a ello.

**Indemnización en caso de fuerza mayor.** — Contrariamente a los principios generales de los artículos 1788 y siguientes del Código civil, las pérdidas, averías o daños ocasionados por fuerza mayor pueden, salvo estipulación contraria en el pliego de condiciones o contrato, dar lugar a una partida a favor del empresario. En esta materia, se entiende por fuerza mayor, de una manera general, un acontecimiento calamitoso de la naturaleza, que era imposible prever en el momento de la celebración del contrato y que hace los trabajos mas difíciles y costosos que lo que hubieran sido en condiciones normales, tales como las tempestades, lluvias torrenciales, crecida extraordinaria de los ríos, epidemias que hayan llevado la desorganización a los talleres y el encarecimiento de la mano de obra, las huelgas, etc.

Los hechos de guerra no entran, generalmente, en los casos de fuerza mayor; ellos dan lugar simplemente a la rescisión de las obligaciones respectivas de los contratantes. Esto mismo resultará cuando en ausencia de todo acontecimiento extraordinario e imprevisto, ocurra una elevación excepcional en el precio de la mano de obra, a menos que este aumento no sea causado por una falta de la Administración.

**Medidas coercitivas contra el empresario.** — Cuando el empresario no se conforme con las condiciones de su contrato, ni observe las disposiciones del Memorandum contentivo de las órdenes de servicio, la Administración puede usar de medidas coercitivas que consisten : 1º en tomar ella misma directamente la ejecución de los trabajos; 2º en la readjudicación de éstos en subasta pública; 3º en la rescisión o resolución del contrato. Entre estas medidas puede escoger libremente la que mas le convenga.

**Recepción provisoria de los trabajos.** — Inmediatamente despues de terminados los trabajos se debe proceder a la recepción provisoria de éstos, con asistencia del empresario. La recepción provisoria no puede, por regla general, ser tácita ni presumirse por la toma de posesión de los trabajos independientemente de circunstancias que la hagan equivalente a la recepción.

**Plazo de garantía.** — La recepción provisoria tiene por efecto hacer correr el plazo llamado de garantía, y el empresario tiene el derecho de exigir a la Administración llevar a cabo dicha recepción, una vez terminados los trabajos.

A falta de estipulación expresa entre las partes, el plazo de garantía es de seis meses, a partir de la fecha de la recepción provisoria, para cierta clase de trabajos, y de un año para las obras de arte. — Durante estos plazos, el empresario permanece responsable de sus obras y está obligado a conservarlas.

**Recepción definitiva.** — Esta tiene lugar a la expiración del plazo de garantía; pero ella no resulta necesariamente del solo vencimiento de este plazo, sino que debe emanar de un acto de la Administración en la misma forma que la recepción provisoria.

La expiración del plazo de garantía, no implica la recepción definitiva de los trabajos, sino que permite al empresario poner en mora a la Administración para proceder a dicha recepción, a efecto de que élla no pueda formular reclamaciones ulteriores por los trabajos de que ya ha tomado posesión sin reservas. No obstante este procedimiento y toma de posesión, la Administración, cuando el empresario ha incurrido en falta, modificando los planes, puede rehusar la recepción definitiva hasta que no se restablezcan las obras conforme a éstos, y hasta puede operar la retención del saldo de la cuenta cuando tal circunstancia esté debidamente comprobada.

La recepción definitiva dá, al empresario, el derecho de reclamar el saldo de lo que le es debido; la restitución de la caución cuando la hubiere entregado y el reembolso de lo retenido como garantía, a condición de justificar que ha cumplido con todas sus obligaciones provenientes de la ejecución de las obras.

La recepción definitiva, tiene por efecto libertar al empresario de toda responsabilidad, fuera de la decenal prevista por los artículos 1972 y 1270 del Código Civil.

**Honorarios de los ingenieros y arquitectos.** — Estos reciben a título de remuneración, ora un sueldo fijo, ora algunos emolumentos proporcionales, a las erogaciones ocasionadas por las obras. Cuando el ingeniero o arquitecto ha cumplido todos los actos de su misión o no ha podido cumplirlos por el hecho de la Administración, tiene derecho a la totalidad de sus honorarios.

Si no ha podido cumplir todas sus obligaciones, como, por ejemplo, si ha muerto antes de haber procedido al arreglo de cuentas, los honorarios deben reducirse proporcionalmente. El abono de los honorarios no tiene lugar, en principio, sino por las erogaciones que han sido hechas conforme a las previsiones del presupuesto y no por los trabajos que no hayan sido previstos en él, a menos que el pliego de condiciones no le haya dejado bastante latitud para suplir las omisiones del presupuesto y proveer a las necesidades que se presenten en el curso de los trabajos.

Las faltas de que el arquitecto puede ser responsable, pueden ocasionar la reducción y aun la supresión de sus honorarios.

Cuando los proyectos sobre las obras hayan sido abandonados, el arquitecto o ingeniero, tiene derecho, en ausencia de una convención en contrario, a percibir algunos honorarios por los planos, proyectos y presupuestos que ha elaborado, a menos que la inejecución de éstos no haya provenido de su falta, como en el caso, por ejemplo, de haber sido rechazado el proyecto por demasiado costoso.

Caso de revocación del mandato remunerado por algunos abonos proporcionales, el ingeniero o arquitecto, tiene derecho, por resolución del contrato, a una indemnización equivalente a sus gastos y a los beneficios de que ha sido privado, a condición de que la revocatoria no sea motivada por las faltas que él haya cometido. En este caso no tiene mas derecho que a los honorarios devengados por los trabajos reconocidos útiles.

## Responsabilidad de los ingenieros, arquitectos o empresarios.

**Responsabilidad decenal.** — La responsabilidad de los empresarios, ingenieros o arquitectos, existe : *a*) durante el plazo de garantía; *b*) posteriormente, durante diez años, conforme al artículo 1792 del Código civil, salvo el caso de dolo o de fraude, en que la acción de responsabilidad dura treinta años.

Durante el plazo de garantía, la responsabilidad por las imperfecciones de las obras, pesa sobre el empresario hasta la recepción definitiva de los trabajos. La responsabilidad posterior a este plazo de garantía, reglamentada por los artículos 1792 y 1270 (Cod. civ.), subsiste aun despues de la verificación y recepción definitiva de los trabajos.

**Prescripción Treintenal.** — En caso de dolo o fraude, la responsabilidad no se extingue sino a los treinta años, que es el lapso fijado por la ley para la prescripción de las acciones por daños y perjuicios.

## Daños causados a la propiedad privada.

Se entiende por daños a la propiedad, todo ataque directo y material a los bienes de otro a consecuencia de los trabajos públicos, sin que haya incorporación al dominio público de ninguna fracción del suelo. No es indispensable, sin embargo, que el daño sea directamente al inmueble mismo para que haya lugar a la indemnización, siendo suficiente que resulte de los trabajos la violación de un derecho de propiedad, esto es, que su ejercicio le sea menoscabado.

Los propietarios cuyas fincas dan a las vias públicas, deben soportar, sin indemnización, los trabajos de refacción o de reparación de las vias públicas que no les causen sino una molestia momentánea, y no constituyan un ataque a los derechos de vista, de acceso, y de pasaje de que gocen. — Es menester, sin embargo, que esta molestia no exceda, por su duración y gravedad un límite normal, y que la Administración haya tomado todas las medidas necesarias para atenuar los inconvenientes resultantes de los trabajos. — Deben soportar, tambien sin indemnización, los trabajos cuya ejecución comporten solamente la pérdida de una simple ventaja de que el propietario habria podido ser privado por el hecho de un tercero sin responsabilidad para éste, como por ejemplo, si los trabajos han dado por resultado privar a un inmueble de las vistas de que gozaba, de la facultad de recoger las aguas pluviales que caen sobre los caminos, etc. — El perjuicio proveniente de una servidumbre legal, tal como la que grava las propiedades vecinas a los cementerios, no da lugar a ninguna indemnización a favor de los dueños de éstas.

Fuera de los casos expresados, los vecinos de las vias públicas, que experimenten un daño a consecuencia de la ejecución de los trabajos en las vias de comunicación, pueden, en principio, reclamar una indemnización; tienen este derecho, por ejemplo, cuando les hayan cerrado una via pública a cuyo uso tenian derecho, así como tambien cuando, por los cambios de nivelación, se obstruyan las vistas y claridad de un inmueble; se produzca su descalzamiento o enterramiento, quedando aquél mas alto o mas bajo y por supuesto si ademas queda comprometida su solidez, y, por tales motivos, depreciada la propiedad.

**Indemnización.** — Para reclamar una indemnización por los daños ocasionados por la ejecución de los trabajos públicos, es menester, en principio, haber sufrido personalmente un perjuicio. Esta indemnización es debida generalmente al que era propietario en el momento del daño.

La indemnización debe comprender todo el perjuicio causado al propietario por la depreciación del inmueble y la utilidad de que ha sido privado, tales como la pérdida de arrendamientos, gastos de mudanzas, etc.

## Trabajos privados o particulares.

Todos los trabajos de que esten encargados los ingenieros o arquitectos, bien sean públicos o privados, deben practicarse de acuerdo con los principios de la ciencia. La impericia en su ejecución, afecta su responsabilidad, pues las relaciones de las partes en materia de arrendamiento de servicios o de obras, en general, estan determinadas por las reglas del derecho en lo referente a obligaciones.

En virtud del principio establecido sobre libertad de contratos, los particulares pueden celebrar libremente sus convenciones para la construcción de sus obras, siendo en estos casos el contrato la ley que regula sus relaciones juridicas. — Este derecho de contratación, está limitado únicamente por las leyes en cuya observancia estan interesados el órden público y las buenas costumbres, las cuales no pueden derogarse ni relajarse por convenios particulares.

Para la validez del contrato, es menester, que los contratantes sean capaz de obligarse, conforme al derecho comun. Asi el menor, no emancipado, no puede arrendar sus servicios sin el consentimiento de su padre, si está bajo la patria potestad, o de su tutor si está bajo tutela. La mujer casada tiene necesidad, a este efecto, de la autorización de su marido. — La ausencia de consentimiento o los vicios de éste (error, violencia, dolo) entrañan la nulidad del contrato de arrendamiento de obras o servicios, conforme al derecho comun.

Nadie puede arrendar sus servicios sino por un tiempo limitado o para una obra determinada, pues está prohibida toda convención por la cual una persona arriende sus servicios por toda la duración de su vida.

## Accidentes del trabajo.

Se entiende por accidentes de trabajo, un golpe al cuerpo humano, proveniente de la acción súbita y violenta de una fuerza exterior que le cause daño. Asi, toda lesión del organismo, aparente o no aparente, interna o externa, superficial o profunda, constituye un accidente.

Los accidentes sobrevenidos a los obreros y empleados en los trabajos de que se ocupan, están sometidos, desde el punto de vista de las reparaciones civiles, a un régimen especial y excepcional. El principio en que descanza dicho régimen, es que la victima del accidente o sus representantes, tienen derecho a demandar del jefe de la Empresa, una indemnización sin tener que justificar que éste ha incurrido en falta, apartandose asi del principio general, establecido por el Código civil, que requiere que haya habido falta de parte de la persona de quien se pretende exigir alguna responsabilidad.

Por virtud del régimen excepcional de que tratamos, la responsabilidad existe por el solo hecho del accidente, considerado como una consecuencia directa del ejercicio de la profesión; es lo que se llama el principio del riesgo profesional. Inversamente, y siempre en virtud del mismo principio, la falta de la victima no es motivo para exonerar de esta indemnización al Jefe de la Empresa.

Para que un accidente de trabajo de lugar a una indemnización, es menester que sobrevenga por el hecho del trabajo de que estaba encargado la victima. La falta de ésta, o del empresario, no se toma en consideración, sino para modificar el *quantum* de la indemnización, la cual será reducida, si la falta emana del obrero, o mayor, si emana del patrón.

Las indemnizaciones comprenden dos elementos : *a*) El pago del precio de las medicinas, honorarios medicos y funerarios; *b*) El pago de los salarios perdidos por el hecho del accidente.

Para el cálculo de las indemnizaciones destinadas a suplir el salario perdido, hay que atender a la naturaleza y consecuencias del accidente. Si se trata de una incapacidad de trabajo puramente temporal, el obrero tiene derecho, hasta su curación, a la mitad del salario que ganaba en el momento del accidente; pero si la incapacidad es permanente, la victima tiene derecho a una renta vitalicia. En caso de muerte, el conyuge, los descendientes y ascendientes, tienen tambien derecho a esta renta.

Debe servir de base para la renta citada, en caso de incapacidad permanente parcial, la mitad de la reducción sufrida por el salario a consecuencia del accidente; en caso de incapacidad permanente absoluta, la base es igual a las dos terceras partes del salario perdido.

Los encargados, empresarios, administradores, etc., cubren generalmente a sus obreros y empleados y se descargan a su vez de dichas responsabilidades, por medio de polizas, de seguros (por accidentes, etc.) tomadas en una compañia bien reputada.

## Vias de comunicación.

Las vias de comunicación han sido establecidas en interes público y comprenden las calles, rutas y caminos de diferentes clases.

En principio, una via no es pública, sino cuando ha sido el objeto de un acto administrativo que la coloca en la categoria de tal. Este acto, que lleva el nombre de clasificación, determina el estado civil de la via pública, el régimen administrativo al cual será sometida y la persona moral a quien pertenezca.

Las vias son principales ó secundarias; las primeras las forman las rutas nacionales y departamentales, y, las otras, los caminos vecinales. A excepción de los caminos rurales de los particulares, todas las vias de comunicación forman parte del dominio público y son, por consiguiente, inalienables e imprescriptibles. Las rutas nacionales son del dominio público del Estado, y, las departamentales, del dominio público departamental. Todas las otras vias de comunicación son del dominio público municipal.

La apertura de las vias públicas no puede verificarse sino despues del cumplimiento de las formalidades establecida por la ley sobre expropriación por causa de utilidad pública, es decir : despues de investigación, declaración de utilidad pública, juicio de expropiación y pago previo de la indemnización consiguiente.

### Anchura de las vias públicas. — Delimitación. — Ensanches.

Como las vias son del dominio público, es a la Administración a quien corresponde fijar el ancho y los limites de las diversas vias públicas. La anchura se determina por las autoridades competentes quienes generalmente los fijan por el acto mismo de clasificación, de acuerdo con las necesidades del tráfico.

**Delimitación.** — Los limites de las vias públicas son determinados por los alineamientos trazados por las autoridades administrativas competentes. Estos tienen por objeto principal trazar la linea separativa del dominio público del de las heredades privadas, y pueden ser fijados, sea por actos especiales individuales, cuando un vecino pide a la Administración indicarle el limite del dominio público con su propiedad, sea por la Administración misma cuando ésta ordena, como medida general, trazar los limites de una via pública en toda su extensión, o de todas las vias existentes en una Municipalidad.

Es importante distinguir los alineamientos individuales de los planos generales de alineación, porque los poderes de la Administración en el segundo caso son mas extensos que en el primero; en éste el alineamiento individual no puede hacerse, sino conforme a los limites actuales de la via pública, mientras que, por los planos generales de alineamientos, la Administración tiene un medio para operar el ensanche de las vias públicas, gravando la propiedad privada con muy onerosas servidumbres. — En este último caso, la alineación implica una verdadera expropiación, pues el ensanche se hace a costa de la propiedad del vecino una parte de la cual va unirse a la del dominio público :

**Efectos de los proyectos generales de alineación.** — Los efectos de estos planes sobre las propiedades vecinas difieren, segun que se trate de simples

terrenos o de terrenos donde existan construcciones, y segun la naturaleza de las vias públicas.

**Simples terrenos.** — Si se trata de vias urbanas, la publicación del proyecto tiene por efecto inmediato someter los terrenos comprendidos en los alineamientos a los reglamentos de la grande o pequeña via, gravandolos con una servidumbre. De aquí resulta que todo acto ejecutado por el propietario sobre esos terrenos, sin autorización, constituye una contravención de grande o de pequeña via, segun su categoria. Importa poco que el propietario no haya recibido notificación individual del proyecto de alineación, o que la Administración no haya pagado aun la debida indemnización. La publicación del proyecto tiene los efectos de una declaración de útilidad pública, pero no constituye un juicio de expropiación, por el cual la propiedad del vecino pasa al dominio del expropiante; el derecho de propiedad de aquel, sobre los referidos terrenos, subsiste hasta el dia en que, en ejecución del proyecto, el propietario recibe de la autoridad competente un decreto especial de alineación trazando el limite entre su heredad y la via pública. — Es entonces que nace el derecho a la indemnización; ésta se pagará al propietario de acuerdo con el valor del terreno cedido a la via publica, sin tomarse en cuenta la depreciación que haya podido sufrir la otra parte de la misma propiedad que resta en poder del expropiado.

**Terrenos donde se edifica o construye.** — Los efectos del plan de alineamiento en cuanto a los terrenos donde existan construcciones, son siempre los mismos ya expresados, cualquiera que sea la via pública de que se trate. — En todos los casos en que, por efecto de un plan general de alineación, una construcción se encuentre en pie sobre la via pública, la aprobación general de este plan no entraña la incorporación inmediata de dicha construcción a la via pública. Esta incorporación no se produce y el derecho a la indemnización no nace en provecho del propietario, sino cuando la construcción ha sido demolida voluntariamente o por causa de vetustez.

## Regimen de las propiedades limitrofes a las vias públicas.

La contigüedad a las vias públicas entraña para los inmuebles limitrofes, ventajas, por una parte, y por otra obligaciones. Estas últimas, conocidas con el nombre de servidumbres de via, se aplican tanto a las construcciones como a los terrenos y varian segun la naturaleza de la via pública. Las unas son generales; las otras son especiales a ciertas vias. — Estas cargas, impuestas a los dueños de esas propiedades contiguas, tienen por objeto : las unas, asegurar la conservación del dominio público en toda su integridad; las otras, asegurar a los transeuntes que usen esas vias públicas la seguridad y comodidad de la circulación.

La mas importante de estas servidumbres es la de la alineación de que ya hemos hablado.

**Derechos sobre las vias públicas.** — Los dueños de las propiedades contiguas o limitrofes a las vias públicas, tienen sobre éstas ciertos derechos especiales que consisten : derecho de acceso, derecho de vista y derecho de desagüe.

El derecho de vista y de acceso los facultan para abrir en los muros de la fachada de sus inmuebles algunas puertas y ventanas, sujetandose para tales operaciones a lo que tengan dispuesto sobre el particular las Ordenanzas o leyes Municipales. — El derecho de salida de las aguas, se entiende solamente de las pluviales, que los propietarios pueden derramar sobre las vias públicas (las que caigan sobre sus fincas), bajo las condiciones determinadas por los reglamentos de policia.

## Servidumbre en general. — Definición. — Caractéres.

La servidumbre es una carga impuesta a un predio para uso y utilidad de otro perteneciente a diferente dueño. Ella es un derecho con relación al propietario del fundo dominante, y una obligación o carga con relación al propietario del fundo sirviente. — Este derecho y esta carga tienen un caracter real y de tal suerte estan ligados a la existencia de uno y otro inmueble, que no les afecta las mutaciones que pueda sufrir la propiedad de alguno de éllos. Son tres las condiciones caracteristicas de toda servidumbre predial : *a*) la existencia de dos heredades, de las cuales la una presta el servicio, y la otra lo recibe; *b*) la existencia de dos propietarios, dueño el uno del predio dominante, y dueño el otro del predio sirviente; y *c*) la causa o el fin de la servidumbre, esto es, el uso y utilidad del predio que goza de la misma.

Tras de estas nociones generales, viene la clasificación de las servidumbres derivadas ya de la situación natural de los lugares, ya de las obligaciones impuestas por la ley, ya de los convenios celebrados entre los particulares, distinción esencial, y que constituye el objeto de varias disposiciones legales.

**Servidumbres que se derivan de la situación de los lugares.** — Por el orden natural de las cosas, los campos inferiores tienen que recibir las aguas que huyen de los campos superiores. Por tanto el dueño del campo inferior no podrá librarse de esta servidumbre que es una carga impuesta por la naturaleza, no pudiendo levantar ningun dique que impida la corriente. El dueño del campo mas alto no puede agravar la servidumbre, ni cambiar el curso de las aguas de modo que perjudique al propietario del campo mas bajo. Esto por lo que respecta a las aguas que corren naturalmente y sin trabajo del hombre. El que tiene un manantial en su predio, puede usar de él como mejor le parezca, salvo el derecho que tal vez hubiese adquirido el dueño del predio inferior por convenio o por prescripción. — El dueño del manantial no podrá, empero, cambiar su curso, cuando la fuente suministra a los habitantes de un pueblo, aldea o caserio, el agua que les es necesaria; solo tendrá facultad para pedir una justa indemnización, que será regulada por expertos, con tal que los habitantes no hubiesen adquirido o prescrito el uso que tienen de la fuente.

Aquel por los lindes de cuya heredad pase un rio, puede aprovecharse de sus aguas a su paso para regar sus tierras. Si la corriente atraviesa la heredad, el dueño de ésta podrá tambien aprovecharse de ellas en todo el espacio que atraviesen, pero con obligación de volverla a su curso ordinario a la salida de sus propiedades. Estan exceptuadas aquellas aguas que la ley sobre la distinción de los bienes declara que pertenecen al dominio público. — El uso de estas diversas facultades puede encontrar varios obstáculos, pero siempre que se promuevan contiendas y litigios entre los diversos dueños de las tierras que intenten beneficiarse de las aguas, se procurará conciliar los intereses de la agricultura y de la industria con el respeto debido a la propiedad, no perdiendo jamas de vista los reglamentos locales y particulares acerca el curso y el uso de las aguas.

Todos los dueños pueden cerras sus fundos, a menos que deban la servidumbre de paso. La necesidad de los lindes produce naturalmente la facultad de acotar las heredades; y esto deberá hacerse a expensas comunes.

**Servidumbres establecidas por la ley.** — Las servidumbres que establece la ley tienen por objeto la utilidad pública o comunal o la de los particulares. Las primeras constituyen obligaciones o cargas impuestas, en interes general, a las propiedades y a los propietarios mismos, por las leyes o los reglamentos. El Código civil no menciona sino dos servidumbres de utilidad pública, pero esta enumeración no es mas que enunciativa. Las principales servidumbres de utilidad publica son 1º las que tienen por objeto las calzadas que ha de haber a lo largo de los rios navegables o flotables; 2º las que se refieren a la construcción o reparación de caminos y otras obras públicas o comunales; 3º la prohibición de construir a cierta distancia de los cementerios y plazas de guerra; 4º la de observar las distancias prescritas relativas a ciertos trabajos cerca de las lineas ferroviarias; 5º la de dejar ejecutar los trabajos necesarios para la explotación de las minas; 6º la prohibición de hacer exploraciones de minas cerca de las habitaciones; 7º la de practicar excavaciones en cierto perimetro alrededor de las fuentes minerales o termales; 8º la de alineación, etc., etc.

En principio, a menos de una disposición formal, el establecimiento de las servidumbres de utilidad pública no da derecho a ninguna indemnización, pues la regla segun la cual nadie puede ser expropiado sin justa y previa indemnización no se aplica sino a la cesión de la propiedad por causa de utilidad pública.

Las servidumbres establecidas por la ley en provecho de los particulares son, segun el Codigo civil, las relativas a la medianeria de las paredes, zanjas, etc.; la distancia y obras intermediarias requeridas para ciertas construcciones; a las vistas sobre la propiedad del vecino; a la caida de las aguas de los techos y al derecho de pasaje en caso de un predio enclavado.

**Medianeria.** — La medianeria es una especie particular de copropiedad aplicada a los objetos que sirven de separación entre dos fundos contiguos, especialmente a las paredes, muros, zanjas, setos y vallados. Estos estan gravados, en provecho de dichos fundos, de una servidumbre de indivisión forzada que constituye una excepción al principio general que establece que nadie está obligado a permanecer en comunidad.

Así en las poblaciones como en los campos, se presume medianera, a no ser que haya prueba en contrario, toda pared divisoria de patios y jardines o bien sea cerca de los campos, y en los edificios hasta donde llega el menos alto. — La reparación y construcción de una pared medianera corre a cargo de todos los que tienen derecho en ella y en proporción a este derecho. — Sin embargo todo comunero de una pared medianera puede excusarse de contribuir a su reparación o construcción, renunciando al derecho que le compete, con tal que la pared medianera no sostenga un edificio que le pertenezca.

Todo dueño de una heredad contigua a una pared o muro, tiene la facultad de hacerlo medianero, reembolsando al propietario del muro la mitad de su valor y la mitad del valor del suelo sobre que ha sido construido. — Todo condueño puede edificar sobre la pared medianera y apoyar en ella vigas; puede levantarla a su costa, pero sino está en estado de sostener la elevación que quiere dársele, el que quiera levantarla deberá renovarla por entero a expensas suyas; y si quiere darle mayor anchura, debe tomarla de su terreno. El vecino que no contribuyó a la elevación de la pared, puede hacerla medianera pagando la mitad de su costo y del suelo que debió poner su vecino, si la hizo más ancha.

Las obligaciones de los propietarios de un muro medianero son, de una manera general, las mismas de toda comunidad; ellos deben velar por la conservación del muro y abstenerse de todo lo que pueda perjudicarlo.

Cuando los diferentes pisos de una casa pertenecen a diversos dueños, si los títulos de pertenencia no establecen el modo como deben hacerse las reparaciones y construcciones, se haran del modo siguiente : las paredes maestras y el tejado quedan a cargo de todos los dueños a proporción del valor que tenga el piso que a cada uno de ellos pertenece; el dueño de cada piso reparará y reconstruirá el suelo que pisa; el dueño del primer piso debe hacer la escalera que a él conduce; el dueño del segundo piso debe hacer la que vá desde el primero hasta el suyo, y asi en los demás.

Cada uno de los propietarios tiene un derecho de propiedad exclusiva y absoluta sobre el piso que le pertenece, y puede, por consiguiente, hacer todos los cambios que le convengan, a condición de abstenerse de ejecutar todo aquello que sea perjudicial a los otros copropietarios de la casa.

**Distancias y obras intermedias.** — No se permite plantar arboles de tronco alto, cerca de una pared medianera, que no sea a la distancia prescrita por las leyes. El vecino podrá exigir que sean arrancados los plantados a menor distancia. Aquel sobre cuya heredad se extiendan las ramas de los arboles del vecino, puede obligar a éste a que las corte. — Si las raices se extienden por su heredad, tiene derecho de cortarlas por sí mismo .

Los arboles que se hallan en el seto medianero, son comunes como el mismo seto, y uno y otro vecino pueden exigir que sean cortados.

No se pueden construir letrinas, chimeneas, fraguas, hornos, abrir pozos ni poner materias corrosivas, etc., cerca de una pared sin dejar las distancias prescritas en las leyes y reglamentos.

**Vistas sobre la propiedad del vecino.** — Ningun vecino puede, sin consentimiento del otro vecino, hacer en la pared medianera ventana alguna ni otra clase de abertura. El dueño de una pared que no sea medianera, aun cuando ella se levante al lado mismo de la heredad de otro, puede abrir en dicha pared lumbreras o ventanas con red de alambre y vidriera que no pueda abrirse. Las mallas de la red de alambre deberan tener a lo mas un decimetro y el marco de la vidriera deberá ser clavado; estas aberturas deberan hacerse a veinte y seis decimetros sobre el piso del cuarto que quiera alumbrarse, si es al nivel de la calle; y a diez y nueve decimetros sobre el piso, si es para los superiores.

Las vistas propiamente dichas son las que dan sobre la heredad del vecino; pueden ser rectas u oblicuas. Las primeras son las que existen en un muro paralelo a la linea de separación de las dos heredades; las segundas, son las que se encuentran en un muro que forma angulo con esta linea. Cuando los dos fundos estan situados sobre el mismo alineamiento, no hay vista recta ni oblicua; sin embargo, si uno de los propietarios construye un balcon, resultará una vista oblicua. — Las vistas no pueden abrirse sobre un muro sino cuando este se encuentre a cierta distancia de la linea separativa de las dos heredades; esta distancia varia segun que la vista sea recta u oblicua : diez y nueve decimetros para las primeras y seis decimetros para las segundas. — Las distancias de que hablamos, deben contarse desde el fundamento exterior de la pared en que se ha hecho la abertura, y si hay balcones u otras obras de vuelo, desde su linea exterior hasta la linea divisoria de las dos propiedades.

**De las aguas que caen de los tejados.** — Los propietarios deben hacer sus tejados de manera que las aguas lluvias caigan sobre su terreno o sobre un camino publico; no pueden dirijirlas sobre el predio de su vecino, pero una vez caidas en su propio suelo, el propietario de éste no está obligado a impedir que se extiendan sobre la propiedad del vecino por efecto de la pendiente natural del terreno.

**Derecho de paso.** — La servidumbre legal de paso existe en provecho del propietario cuyo fundo está enclavado. El dueño de una heredad, que por hallarse cercada por otras, no tiene ninguna salida al camino público, puede reclamar que se le conceda un paso por las heredades de sus vecinos para poderla cuidar, con la obligación de indemnizarles a proporción del daño que les pueda ocasionar. — Por lo regular se abrirá el paso por donde sea menor la distancia para llegar al camino público, debiendo atenderse a que cause el menor daño posible en las heredades por donde debe pasar.

La servidumbre de paso no dá al propietario del fundo enclavado la propiedad del terreno que sirve de pasaje; el dueño del fundo gravado conserva la libre disposición de su terreno, con la sola limitación de no interrumpir el ejercicio del derecho de paso. — La extensión de este derecho se regla de acuerdo con las necesidades actuales de la explotación del fundo enclavado; caso de desacuerdo entre las partes debe ocurrirse a una experticia al efecto de verificar estas necesidades y saber si dicha explotación reclama un camino carretero o simplemente uno mas restringido.

**Servidumbres establecidas por el hecho del hombre.** — Pueden los propietarios establecer sobre o en favor de sus heredades las servidumbres que quieran con tal que éstas no sean contrarias al órden público. El uso y extensión de estas servidumbres se regulan a tenor de lo prescrito en las escrituras de su constitución, y en su defecto por las reglas siguientes :

Las servidumbres se establecen para el uso de los edificios o para el de las tierras. Las primeras se llaman servidumbres urbanas, sea que los edificios a cuyo favor fueron constituidas, esten en o fuera de población; las segundas se llaman rústicas. Las servidumbres son continuas o discontinuas; las continuas son aquellas cuyo uso puede ser continuo sin necesidad de un hecho positivo del hombre : tales son los acueductos, las vistas y otras de semejante especie. Las discontinuas son las que, para cuyo ejercicio no se necesita un hecho positivo del hombre : tales son los derechos de pasaje, sacar agua, pastaje y otros semejantes.

Las servidumbres son visibles o no visibles. Las primeras son las que se descubren por alguna obra exterior, como una puerta, una ventana, un acueducto; las segundas aquellas que no se manifiestan por ninguna señal visible, como por ejemplo, la de no edificar en una heredad, o de no poder edificar mas que hasta cierta altura.

Las servidumbres continuas y visibles se adquieren por título o por la posesión de treinta años. Las continuas no visibles y las discontinuas, sean o no visibles, pueden solo establecerse por titulos.

Al establecerse una servidumbre se reputa concederse todo lo necesario para su uso. Asi la servidumbre de sacar agua de una fuente agena comprende necesariamente el derecho de pasaje.

Aquel a quien se debe una servidumbre tiene derecho a hacer todas las obras necesarias para usar de ella y conservarla.

## Ingeniero arquitecto.

Los arquitectos estan obligados a observar las leyes y reglamentos administrativos sobre construcciones. Son responsables para con el propietario de las consecuencias que resulten de la inobservancia de las leyes y reglamentos concernientes a las vias públicas y a la contigüedad de los predios.

Como autor de sus planos y presupuestos y director de trabajos, tiene un derecho privativo sobre su obra en virtud de las leyes relativas a la propiedad intelectual. — Cuando sus honorarios no han sido convenidos de antemano por contrato, quedan éstos sujetos a la apreciación de los Tribunales.

## Deslinde de tierras.

El deslinde es una operación que tiene por objeto fijar la linea divisoria de dos fundos contiguos y determinar con la ayuda de signos materiales llamados mojones, la linea de separación que se busca, de acuerdo con los títulos respectivos exhibidos por las partes.

Todo propietario puede obligar a su vecino al deslinde de sus propiedades contiguas, ocurriendo a la autoridad judicial respectiva a quien incumba conocer del asunto, segun las leyes de procedimiento civil. — La acción de deslinde puede ser intentada por cualquiera que tenga un derecho real sobre el inmueble, especialmente por el propietario, el usufructuario, el nudo propietario, el enfiteuta, el usuario y el copropietario indiviso.

Dos hipotesis pueden presentarse : 1º las partes estan de acuerdo sobre el limite de sus heredades, procediendose entonces solamente a fijar la delimitación por la colocación de los mojones; 2º sin discutir la propiedad ni los titulos presentados, las partes no estan de acuerdo sobre los límites de sus fundos. En este último caso el Juez ordena el deslinde por los expertos que él designe, y, el dia señalado previamente para proceder, que será notificado a todos los colindantes, el Juez concurrirá en persona al deslinde y designará los lugares donde deban situarse los mojones que señalen los linderos despues de haber recibido el informe de los expertos.

Cuando alguno de los colindantes se oponga a la designación de algun lindero, presentará en el acto del deslinde el titulo de sus tierras, o algun instrumento supletorio suficiente, y el Juez, si no pudiere cortar en conciliación la disputa, despues de examinar los titulos y oir a los prácticos, si le pareciere necesario, fijará un lindero provisional, haciendo la debida apreciación del mérito de los autos y del resultado de sus observaciones sobre el terreno; lindero que se respetará mientras se decida la cuestión suscitada en el respectivo juicio motivado por la referida oposición del colindante.

La diligencia del deslinde, haya o no oposición, la firmaran el interesado y todos los colindantes que hubieren concurrido, con el Juez y el Secretario; y si alguno de aquellos no supiere o no quisiere firmar, se expresará asi, advirtiendose al que no quiera firmar que esta falta no le favorecerá de modo alguno.

En la acción de deslinde, todas las partes son respectivamente demandantes, y cada una de ellas debe suministrar la prueba de sus pretensiones. Si existe un titulo emanado del autor comun de las partes, el Juez debe dictaminar de acuerdo con lo expresado en dicho título, a menos que los limites no hayan sido modificados por una convención ulterior. A falta de tal título, se admite que cada parte pueda invocar cualquiera otro documento, en el caso mismo de que su adversario no figure en él, salvo al Juez determinar si halla razon para ello.

Los gastos de compra y de plantación de mojones se dividen de por mitad entre los propietarios interesados, pero los de mensura deben, segun la opinión dominante, repartirse entre los propietarios proporcionalmente a la extensión de sus fundos. Si ha habido oposición durante la operación de deslinde, los gastos que ocasione este juicio debe soportarlo únicamente la parte que sucumbe en el pleito. Los otros gastos del deslinde se repartirán igualmente entre todos los interesados.

La supresión o alteración de los mojones que determinan los linderos, dá lugar a una acción interdictal y a otra correccional; y tambien a la indemnización de los perjuicios ocasionados.

## Metrologia general y su aplicación.

La metrologia general tiene por objeto la medición racional y sistemática de las diversas cantidades que intervienen en los fenomenos naturales, siendo las leyes y principios que la rigen aplicadas a la medición de las materias objeto de la industria y del comercio.

La metrologia aplicada se funda en el sistema métrico decimal, cuyas unidades fundamentales son el metro y el gramo. El primero, llamado metro patrón, es una regla de platino irradiado al 10 % con sección en forma de X, de 20 mm. del lado, que a 0º C define esa longitud tipo; el segundo, o sea el gramo, es la unidad de la masa (equivalente al peso, en un mismo lugar de la Tierra) que se define como la masa de un centimetro cúbico de agua químicamente pura a 4º C, y a la presión normal.

El sistema métrico decimal es obligatorio, que sepamos, en Francia, Alemania, España, Belgica, Italia, Grecia, Holanda, Portugal, Rumania, Servia, Suiza, Austria, Hungria, Suecia y Noruega, Venezuela, Argentina, Perú, Méjico, etc. Es facultativo en los Estados Unidos de America, en el Reino Unido de la Gran Bretaña e Irlanda, en Japón, Turquia, Egipto y Rusia.

Para las diversas unidades del sistema métrico decimal con los símbolos que aconseja y emplea el Comité internacional de Pesas y Medidas, con sus valores en unidades fundamentales y sus relaciones con las de los diversos paises. Véanse pags 229 á 238.

## PENALIDADES

Como el uso de otras pesas y medidas que no sean las establecidas por las leyes constitutivas del sistema métrico decimal, está prohibido; los infractores de las disposiciones legales que lo rigen incurren en las diversas penas que las mismas leyes determinan en sus casos.

### Agua.

El agua, considerada en su sustancia, entra en la categoria de las cosas comunes, no susceptible de apropiación privada; pero las fuentes, los estanques, los lagos, los rios o los mares, que constituyen algunas porciones de la superficie terrestre pueden pertenecer a la colectividad o a los particulares.

De estas diversas categorias del agua, se pueden hacer multiples clasificaciones, segun el punto de vista en que uno se coloque : aguas públicas o privadas, vivas o pluviales, corrientes o estancadas, etc., cuyo régimen está organizado por numerosas leyes.

**Aguas marítimas.** — La mar, no siendo susceptible de ocupación, está clasificada en el número de las cosas comunes. El derecho público reconoce la libertad de la alta mar. Cuanto al mar territorial, se admite al contrario que ella hace parte del territorio del pais que bañan sus aguas; lo mismo está admitido respecto de los mares cerrados, abras, puertos y radas.

Sobre el mar territorial, el Estado ejerce todos sus derechos de soberania, jurisdicción, cabotaje, pesca, alta policia, etc.; él organiza las aduanas y los peajes; reglamenta la navegación, la admisión de navios en los puertos y radas, etc. Se admite que el derecho de jurisdicción se ejerce sobre el mar territorial hasta el punto donde puede llegar una bala de cañon.

Las playas del mar pertenecen al dominio público, lo mismo que el aluvión y el terreno que deja en seco.

**Rios navegables o flotables.** — Son los que tienen caudal suficiente para el tráfico de barcos aunque esta capacidad provenga de la naturaleza misma o de trabajos de arte.

La navegabilidad tiene como consecuencia necesaria la propiedad, y asi estos rios forman parte del dominio público, siendo por tal motivo inalienables e imprescriptibles.

Sólo a la Administración corresponde el derecho de comprobar si un rio es navegable.

Los limites de un curso de agua navegable, hasta su desembocadura en el mar, estan determinados por la autoridad competente. Las bases son complexas : se atiende especialmente al volumen de las aguas, saladura, constitución geológica de sus orillas, etc. El principio de la delimitación es que el lecho del curso de agua comprende todo el terreno que cubren las aguas corrientes hasta su borde antes de desbordarse. Poco importa que esta elevación de las aguas sea debida a las lluvias, o, a la influencia de las mareas ordinarias.

Los terrenos recubiertos por un desbordamiento no son adquiridos por el dominio publico; el ribereño conserva sus derechos para retomar su ejercicio cuando las aguas se retiren. Si la inundación se prolonga largo tiempo, resulta una cuestión de hecho que debe apreciarse para saber si en este caso hay simple desbordamiento o cambio de lecho. Los ribereños tienen contra dicho decreto un recurso contencioso por incompetencia, inobservancia de formas legales, exceso de poder, si el trazado de los limites es incorrecto, por torcimiento de poder, si la delimitación es hecha con otro interes que no sea el libre curso de las aguas y de la navegación.

Un decreto de delimitación no liga a las jurisdicciones administrativas que tienen el derecho de declarar que los limites han sido mal apreciados o que ellos han sido modificados con posterioridad al decreto.

Determinados por una situación de hecho los limites de un rio, son susceptibles de modificarse por el cambio de esta misma situación. El ribereño soporta las mudanzas del curso del agua que le son perjudiciales, como se beneficia de aquellas que le son ventajosas, cuando la causa de estas mudanzas son naturales. Si, al contrario, la modificación de los limites proviene de una elevación de la ribera debida a trabajos de arte, constituye una expropiación que dá lugar a indemnización. El Estado puede tambien ser obligado a indemnizar en razon de las corrosiones de la ribera y otros desgastes resultantes de trabajos públicos; pero, en estos casos, la indemnización no es por expropiación, sino simplemente por daños. Si el inmueble, al propio tiempo que sufre un daño, se beneficia de un mayor valor

por haberse aprovechado, por ejemplo, de un aluvión resultado de los mismos trabajos públicos, hay lugar a efectuar una compensación.

**Trabajos diversos, ocupaciones, construcciones.** — Los rios navegables y sus dependencias, como pertenecen al dominio público, su guarda esta confiada a la Administración, y, sin la autorización de ésta, no puede ejecutarse ningun trabajo y practicar ninguna toma de agua. — El público puede ejercer libremente sus derechos naturales, tales como el de sacar agua, lavar, dar de beber al ganado, etc., a condición de observar los reglamentos de policia y de no hacer ningun establecimiento. Los ribereños no tienen, por su calidad de tales, ningun derecho privilegiado.

Los Prefectos tienen el derecho de autorizar, de acuerdo con la opinión o la proposición de los ingenieros, y bajo la autoridad del Ministro : 1º las tomas de agua por medio de máquinas que no tengan por efecto modificar el regimen de las aguas; 2º los establecimientos temporales aun cuando tengan por efecto modificar el regimen o el nivel de las aguas. — La duración de estas autorizaciones temporales debe ser fijada en el acta de concesión y no puede pasar de dos años. Los otros establecimientos sobre un curso de agua navegable no comprendidos en la categoria de los indicados, no pueden ser autorizados sino por el Presidente de la Republica.

No es permitido estacionar u ocupar un lugar cualquiera sobre el dominio público, sin autorización acordada por el Prefecto en debida forma.

Una instalación no autorizada sobre el dominio fluvial, constituye una infracción y cualquiera que sea su duración, no cambia de carácter ni podria engendrar ningun derecho. La supresión o modificación de un establecimiento, puede ser ordenada por la autoridad competente cuya autorización era necesaria para la obra, debiendo proceder en la misma forma y con las mismas garantias exigidas para dicha autorización. Es menester, sin embargo, hacer reserva de aquellos casos en que la medida se impone por una urgencia absoluta. — La decisión administrativa no impide a los interesados hacer valer los derechos que crean tener a una indemnización.

Si, en principio, la Administración tiene un poder discrecional para suprimir o modificar los establecimientos autorizados, la jurisprudencia mas reciente admite que aquella no debe hacer uso de ese poder, sino en interes de la navegación o del libre curso de las aguas y aun para la conservación del Dominio. Un acto que se inspire en otros motivos, puede ser anulado por desvio de poder.

**Caminos de sarga.** — Los ribereños de una corriente de agua navegable o flotable, deben soportar algunas servidumbres que se ejercen, en principio, sobre ambas riberas. Estas servidumbres consisten principalmente en dejar un espacio libre en las riberas de 7 metros 80 para camino de sarga, y libre de construcciones, plantaciones, etc., un espacio suplementario de 1 metro 95 sobre el borde interno del camino. Estas distancias pueden reducirse, cuando el interes de la circulación fluvial lo permite. Corresponde al Ministro de Trabajos Públicos, tomar las medidas a este efecto. El camino de sarga sirve para la circulación de los animales necesarios para remorcar las naves. Tambien debe dejarse sin construir, cerrar o plantar, un espacio de 3 metros 25 que permita a los marineros llegar a tierra si las necesidades lo requieren.

El camino de sarga, no pertenece al dominio público, sino al ribereño, quien readquiere su libre uso cuando el rio deje de ser navegable; él readquiere tambien el libre uso de la parte que quede exenta de la referida servidumbre, cuando la autoridad respectiva haya reducido los limites de aquella; pero, en todo caso, tiene derecho a los productos del suelo y del subsuelo.

La servidumbre debe limitarse a su objeto, que es el de permitir la sarga, no pudiendo los marineros agravarla por una instalación permanente o temporal, ni por el depósito de objetos sobre el camino.

Las zonas destinadas al camino se mediran, en principio, a partir de la linea separativa del dominio público y de la propiedad privada, es decir; desde el limite indicado por las aguas corrientes por la orilla antes de cualquier desbordamiento. Cuando la orilla no sea bastante plana para permitir la circulación de los hombres y de los caballos, es, segun la jurisprudencia, a partir de la cresta de las orillas que el ancho debe calcularse.

**Prohibición de extraer materiales.** — Está prohibido extraer sin autorización especial, tierras, arenas y otras materias, a una distancia menor de 11 metros 70 del curso de un rio navegable.

**Contribuciones de los ribereños.** — Los ribereños estan obligados a cooperar a los trabajos de construcción de diques necesarios para la protección de las

regiones vecinas al rio. A este efecto, éllos pueden constituirse en asociaciones sindicales.

Cuando el Estado ejecuta por si mismo dichos trabajos, los ribereños estan obligados a contribuir pecuniariamente; y, en las mismas condiciones, deben contribuir a los trabajos para poner a las poblaciones al abrigo de las inundaciones. Estas cargas incumben a los ribereños de todos los rios sean o no navegables.

Está prohibido construir, sin declaración previa, ningun dique sobre las partes sumergibles de los valles de ciertas riberas especialmente designadas. No se trata en este caso de obtener una autorización, sino de una simple declaración de hacer. — Cuanto a los diques existentes, pueden ser destruidos, mediante una indemnización, si el Ministro los juzga perjudiciales.

**Dragados de rios navegables.** — Estas es una operación que consiste en el conjunto de los trabajos necesarios para devolver su anchura y profundidad naturales al lecho de un curso de agua, embarazado por los casquijos, tierras, enlodamientos, etc. El dragado de los rios navegables y sus dependencias, es de cargo del Estado. Una contribución pecuniaria puede, sin embargo, pedirse a las comunas o municipios, a los propietarios de fábricas y a los ribereños, segun las circunstancias.

Los ribereños estan obligados a soportar los inconvenientes naturales del dragado, las interrupciones de la navegación, paradas de las tomas de agua, los daños que sufran las fábricas, pero nó el depósito sobre sus propiedades, de limos y desechos provenientes de la ejecución de los trabajos. — Ellos tienen derecho a una indemnización cuando les ha sido ocasionado un daño por ejecución defectuosa de los referidos trabajos, y tambien cuando éstos entrañan una modificación en la corriente del rio y un avance sobre la propiedad privada.

**Rios no navegables ni flotables.** — Un curso de agua es de propiedad privada en tanto no haya salido del fundo donde nace la fuente a la cual se asimila; el dueño de dicho fundo puede disponer del agua a su voluntad, pero no le está permitido desviarlas, con perjuicio de los usuarios inferiores.

La jurisprudencia y la mayoria de los autores, consideran que los rios no navegables, en su integridad, es decir, tanto por su lecho como por la masa de las aguas, entran en la categoria de las cosas que no pertenecen a nadie y cuyo uso es comun a todos, reglandose su goce por las leyes de policia. La ley de 1898 no ha sancionado este sistema, manteniendo solo el principio en lo que concierne a las aguas, pero no respecto del lecho del rio que considera accesorio de los fundos ribereños, perteneciendo, por consiguiente, este lecho, a los propietarios de ambas riberas.

Si las dos riberas pertenecen a propietarios diferentes, cada uno de ellos tiene la mitad del lecho del rio. El eje de la corriente de agua, es el limite que separa las heredades ribereñas. Es desde este eje que se cuenta la distancia de dos metros exigidos para las vistas y plantaciones. Si en principio, el eje del curso de agua forma entre ribereños el limite natural, éste es susceptible de modificarse, sea por la convención de las partes, sea por la prescripción. El propietario de una sola ribera puede pues ser, al propio tiempo, propietario de la totalidad del lecho.

El agua ha conservado el caracter de cosa que no pertenece a nadie y cuyo uso es comun a todos; los ribereños tienen sobre el uso de ella derechos privilegiados, pero solamente dentro de los limites establecidos por la ley.

La situación legal de un curso de agua no navegable puede no ser conforme a a ley de 1898. Se reconoce la validez de las concesiones y enagenaciones hechas por los dueños antes de la abolición del régimen feudal. En virtud de estos titulos, un ribereño puede ser propietario del rio, sus aguas y lecho.

El derecho mas importante del ribereño, el es de usar el agua para sus necesidades agricolas e industriales dentro de los limites concedidos por la ley para su ejercicio. El derecho de que aqui se trata, está sometido al control de la autoridad administrativa, cuyos reglamentos estan obligados los ribereños a observar.

La autoridad administrativa interviene en virtud de los reglamentos generales y tambien por decisiones individuales llamadas tambien autorizaciones. Su poder se ejerce con el doble objeto de asegurar : 1º la libre corriente del agua desde el punto de vista de la seguridad pública y de la salubridad; 2º la repartición del agua en interes de la agricultura y de la industria. — Toda intervención con otro fin, está considerada como exceso de poder. — En interes de la seguridad y de la salubridad, el poder de la Administración puede extenderse sobre las aguas que, de una manera general, no esten sometidas al régimen de los rios no navegables : un canal privado, por ejemplo, o un curso de agua antes que haya salido del fundo donde nace la fuente, o a un curso de agua que pertenezca a un particular en virtud de una concesión feudal.

Los reglamentos generales, constituyen la ley del curso del agua o de una sección determinada de aquel. Los ribereños estan obligados a pedir autorización para toda obra, sin mas excepción que para los simples cortes de las orillas que pueden practicar libremente para la irrigación. La autorización no es una manifestación del poder discrecional de la autoridad; ella debe ser acordada cada vez que no se corra el riesgo de lastimar un interes general. Si un derecho es violado por la decisión administrativa, los interesados pueden ocurrir a la via contenciosa...

La autorización acordada atestigua que el derecho pretendido por el ribereño, puede ejercerse sin incovenientes para el interes general. Es desde este punto de vista una especie de visto bueno que nada prejuzga en cuanto al valor del derecho mismo, y no tiene influencia en lo que concierne a los conflictos posibles con los derechos de terceros.

Solo a la autoridad competente corresponde determinar el regimen general de las corrientes de agua no navegables desde el punto de vista de los derrámenes y repartición de las aguas. Sus decretos deben conciliar los intereses de la agricultura y de la industria con el respeto debido a la propiedad.

Los reglamentos de repartición de las aguas no pueden intervenir sino en interes general, para operar una partición entre la agricultura y la industria. Es al Poder Judicial que los ribereños deben pedir los reglamentos de agua concernientes a las situaciones privadas resultantes de titulos, convenciones, prescripciones, etc.

**Dragado de rios no navegables.** — Se procede al dragado de éstos, ora por la acción individual de los ribereños, ora por el empresario, ingeniero o alarife, con quien han tratado los sindicatos o la Administración. Esta tiene siempre un derecho de *control* y puede de oficio hacer ejecutar los trabajos que, dentro del plazo fijado, para la ejecución, no hayan sido comenzados o terminados, debiendo previamente poner en mora, por un requerimiento a los propietarios o empresarios negligentes o recalcitrantes. Durante los trabajos, los ribereños, están obligados a dar paso a los obreros, empresarios, funcionarios y demas agentes encargados de la supervigilancia de los trabajos, y a soportar el depósito de los desechos sobre sus tierras.

Los gastos de dragado comprenden : el costo de los trabajos, las indemnizaciones debidas en razon del ensanche, los honorarios de los que forman los planos y proyectos, los de los agentes y funcionarios de vigilancia. Estos gastos se reparten entre los interesados conforme a los usos y reglamentos, y, si no existen precedentes, proporcionalmente al grado de interes de cada uno.

**Canales.** — Son cursos artificiales de aguas construidos para usos variables. Son publicos o privados y están destinados, ora a la navegación o flotación, ora a la irrigación o al desecamiento, ora al movimiento de maquinarias.

Los canales para la navegación se dividen; en canales propiamente dichos y rios canalizados. — Los trabajos de canalización son ejecutados en virtud de una ley que los declare de utilidad pública.

El Estado puede encargarse de la construcción y explotación del canal, y tambien el Departamento o comuna. En el primer caso, el canal pertenece al dominio nacional, y, en el segundo, al dominio público departamental o comunal. — El Estado puede tambien abandonar su construcción o explotación, o ambas cosas a la vez, a compañias concesionarias.

La autoridad administrativa tiene el derecho de reglamentar los canales.

Un rio no navegable puede ser canalizado en todo o en parte, en su curso. La canalización lo mismo que la creación de un canal, entra en la categoria de los grandes trabajos cuya ejecución no puede tener lugar sin previa declaratoria de utilidad pública.

Los canales de irrigación son de interés general o privado. En el primer caso son construidos como los trabajos públicos, en virtud de una ley o de un Decreto, declarándolos de utilidad pública.

**Estanques y lagos.** — Los estanques y lagos son aglomeraciones de agua, dulces o saladas, no corrientes, teniendo o no desagües naturales o artificiales. La denominación de lagos está reservada a los estanques de vasta extensión.

Los estanques naturales estan sujetos a las leyes de interes general y de salubridad pública. Los estanques artificiales pueden crearse libremente por los particulares dentro de sus heredades, sea con las fuentes que nacen en sus fundos, sea con las aguas pluviales que recojan, etc.

El establecimiento de un estanque no está sometido, en general, a ninguna autorización administrativa. Solo se exige dicha autorización en ciertos casos especiales;

el consentimiento de los propietarios de los fundos inferiores se hace indispensable, cuando la creación del estanque pueda agravar la servidumbre impuesta por el curso natural de las aguas.

**Aguas minerales y termales.** — Las aguas minerales naturales y las aguas minerales artificiales, están reglamentadas por una legislación especial. Su conservación y conducción, están reglamentadas por la ley.

## Vias férreas. — Ferrocarriles y Tranvias.

En principio los ferrocarriles se explotan por concesionarios en virtud de contratos celebrados con el Estado. Esta concesión puede hacerse directamente a la persona o compañia que la solicita o por via de adjudicación pública por medio de una licitación a los que presenten mayores garantias y ventajas.

La duración de las concesiones varia; antiguamente fueron a perpetuidad, pero luego se limitaron a 99 años como máximo de tiempo para el goce de la concesión por el concesionario.

Por contrato celebrado entre el Estado y el concesionario, éste se obliga a ejecutar los trabajos de construcción de la via y sus accesorios, y, una vez terminados los trabajos, tiene derecho el concesionario a indemnizarse percibiendo una remuneración de las personas que se sirvan de la linea para el trasporte y, ordinariamente goza tambien de ciertas ventajas pecuniarias que el Estado le asegura, de acuerdo con la convención celebrada. — En esta se establecen por escrito las disposiciones relativas al objeto de la concesión, a las obligaciones contraidas, a las condiciones de construcción, de mantenimiento y explotación de la via ferrea, a la duración de la concesión, a las condiciones para el rescate y la caducidad, a la tarifa máxima que puede aplicarse para el transporte de los viajeros, de la mercancia, etc.

Las vias férreas son de interés general cuando por su importancia y extensión abarcan varios Departamentos o Provincias; y, de interés local, los establecidos por los Departamentos o los Municipios, quedando comprendidos en estos últimos los tranvias; pero todas están sometidas para la ejecución de sus trabajos, conservación y explotación de la linea al *control* y supervigilancia de la Administración pública nacional, departamental o municipal, segun los casos.

Todos los trabajos principales de construcción de las obras, asi como los complementarios de las mismas, deben ser previamente autorizados por la Administración pública respectiva, despues de haber sido aprobados por ésta los correspondientes planos, proyectos, etc.

La ejecución de los trabajos puede hacerse bajo de una de las tres formas siguientes : 1º el Estado ejecuta por su cuenta los trabajos, sea para explotar él mismo la via, sea para hacerla explotar por una compañia; 2º el Estado adquiere los terrenos y hace los trabajos de *infraestructura*, dejando a una compañia el cuidado de establecer la via y los trabajos de *superestructura ;* 3º una compañia concesionaria ejecuta todos los trabajos y explota élla misma el ferrocarril con la ayuda financiera del Estado. En Francia, el sistema de explotación directa se aplica respecto a la red ferrocarrilera del Estado : el sistema de la concesión está en vigor en lo que concierne a las otras lineas férreas.

Los concesionarios no tienen la propiedad de la obra, sino solamente el goce de la via y de sus accesorios hasta la expiración de la concesión que pasa al Estado, Departamento, o Municipio, segun los casos. Los caminos de hierro son del dominio público y, como las otras vias, son inalienables e imprescriptibles, lo mismo que las Estaciones y otras construcciones necesarias para la explotación que están consideradas como accesorias del suelo. El concesionario que quiera, en el curso de la concesión, ceder sus derechos a un tercero, debe obtener la autorización previa de los Poderes públicos respectivos; una cesión hecha sin esa autorización es radicalmente nula y de ningún efecto.

Las concesiones pueden terminar de cuatro maneras : *a*) por la expiración del plazo por que fué concedida; *b*) por la cesión que se haya hecho de élla; *c*) por la pérdida del derecho por incumplimiento del concesionario; *d*) por el rescate que el Estado haga del ferrocarril y de sus accesorios, de acuerdo con las estipulaciones previstas en el respectivo contrato o en la Ley sobre la materia.

El rescate debe ser efectuado en globo, es decir, que debe ser de la totalidad de las obras. Para fijar el precio del rescate, se suman los productos netos obtenidos anualmente por el concesionario durante los últimos siete años que preceden a la fecha en que va a efectuarse el rescate; luego se deducen los productos netos de los dos años menos favorables, y se busca el producto neto medio de los otros cinco

años; este producto medio forma el montante de una annalidad que deberá ser pagado al concesionario durante cada uno de los años que falten para vencer la concesión.

Las relaciones existentes entre el Estado y los concesionarios exigen que éstos lleven su contabilidad de manera clara y precisa; estas cuentas son de dos especies: unas referentes a los gastos de construcción; y las otras sobre la explotación.

**Medidas de conservación y servidumbres.** — Los caminos de hierro construidos o concedidos por el Estado forman parte de la gran vía, y, por consiguiente, le son aplicables las leyes y reglamentos que la rigen y que tienen por objeto asegurar la conservación de los fosos, taludes, muros y obras de arte dependientes de las rutas; el alineamiento, la corriente de las aguas, la ocupación temporal de los terrenos en caso de reparaciones, las distancias que deben observarse para las plantaciones y altura de los árboles, el modo de explotación de las minas, mineros, hornagueras y arenales, en la zona determinada a este efecto. Son igualmente aplicables a la confección y mantenimiento de los caminos de hierro, las leyes y reglamentos sobre la extracción de los materiales necesarios a los trabajos públicos.

Fuera de un muro de cerca, ninguna otra construcción puede hacerse a una distancia de dos metros de los caminos de hierro. En las localidades donde éstos se encuentren en terraplenes de mas de tres metros sobre el nivel natural del terreno, está prohibido practicar, sin autorización previa, excavaciones en una zona de ancho igual a la altura vertical del terraplén medido a partir del pie de los taludes. Asimismo está prohibido acumular a una distancia menor de veinte metros, rastrojos, cobertizos de paja, pila de heno o cualesquiera otros depósitos de materias inflamables. A una distancia no menor de cinco metros tampoco podrá establecerse depósitos de piedras, u objetos no inflamables, sin la autorización previa de autoridad respectiva. Ella no es necesaria: 1º para formar en las localidades donde el camino de hierro esté en terraplén, depósitos de materias no inflamables cuya altura no exceda al terraplén del camino; 2º para formar depósitos temporales de abonos u otras materias necesarias al cultivo de las tierras.

**Tarifas.** — El Estado interviene en la fijación del precio de las tarifas las que, sin su aprobación, no pueden ponerse en vigor. Una tarifa máxima limita los derechos del concesionario, quien no puede hacer sin homologación ministerial ninguna modificación a aquella.

Las tarifas de los caminos de hierro indican los precios de los transportes por tonelada kilométrica, es decir: el transporte de una tonelada de mercancía por cada kilómetro de distancia. Para los animales, el precio se fija por cabeza y por kilómetro. Se distinguen tres especies de tarifas, a saber: *a*) la tarifa legal al maximum, de la cual el concesionario no puede pasar; *b*) la tarifa general aplicada en el hecho por el concesionario cuyos precios son casi siempre inferiores a los de la tarifa legal máxima; *c*) las taritas especiales que contienen algunas reducciones variables sobre el precio de la tarifa general, segun las circunstancias.

El carácter obligatorio de las tarifas y de las taxas tiene por consecuencia el reembolso de lo que se haya recibido de mas y el derecho para el concesionario al reintegro de lo que haya percibido de menos. El público que no está informado del precio exacto de las tarifas en el momento de la expedición de sus mercancías, puede pagar bajo reserva sin que pueda ser esto un pretexto para rehusarse la expedición de la mercancía.

Entre las tarifas deben distinguirse las referentes a los viajeros, de las de mercancías. También existen para los pasajeros tarifas generales y especiales. Los precios de estas se calculan por kilómetros. Las especiales acuerdan a los viajeros, bajo ciertas condiciones, una reducción del precio de las tarifas generales.

**Conservación y explotación de la vía.** — Los poderes de la Administración pública relacionados con el mantenimiento, la explotación y supervigilancia de los caminos de hierro, continuan durante la existencia de la concesión. En virtud de este principio, el Ministro de Trabajos Públicos, como se llama en Francia, ordena ciertas medidas concernientes al servicio de la vía, al empleo de materiales y al uso de las señales. Solo al Ministro incumbe determinar la necesidad y oportunidad de estas medidas dentro de los limites de sus facultades policiales. En virtud de los reglamentos de esta naturaleza dictados por él, los pasos a nivel, las maniobras de las barreras y de alumbrado, desde el punto de vista policial, se dividen en cinco categorias cada una de las cuales está sometida a reglas especiales.

La explotación de los ferrocarriles, está, generalmente, a cargo de compa-
